A method is proposed for the detection of item bias with respect to observed or unobserved subgroups. The method uses quasi-loglinear models for the incomplete subgroup x test score x item 1 x ... x item k contingency table. If the subgroup membership is unknown, the models are the incomplete-latent-class models of S. J. Haberman (1979). The (conditional) Rasch model is formulated as a quasi-loglinear model. The parameters in this model that correspond to the main effects of the item responses are the conditional estimates of the parameters in the Rasch model. Item bias can then be tested by comparing the quasi-loglinear-Rasch model with models that contain parameters for the interaction of item responses and the subgroups. An example uses data from a test taken by 286 Dutch undergraduates who took a multiplication test using Roman numerals and numbers written out in Dutch. Some of the examinees had received training in multiplying Roman numerals. It was expected that Roman items would be biased, and the procedure confirmed this bias. Five tables present the models and study data. A 55-item list of references is included. (Author/SLD)
Item Bias Detection using the Loglinear Rasch Model

Observed and Unobserved Subgroups

Item Bias Detection using the Loglinear Rasch Model:
Observed and Unobserved Subgroups

Henk Kelderman
A method is proposed for the detection of item bias with respect to observed or unobserved subgroups. The method uses quasi-loglinear models for the incomplete subgroup x testscore x item 1 x ... x item k contingency table. If subgroup membership is unknown the models are Haberman's incomplete-latent-class models.

The (conditional) Rasch model is formulated as a quasi-loglinear model. The parameters in this loglinear model, that correspond to the main effects of the item responses, are the conditional estimates of the parameters in the Rasch model. Item bias can then be tested by comparing the quasi-loglinear-Rasch model with models that contain parameters for the interaction of item responses and the subgroups.
Introduction

Educational or psychological tests are biased if the test scores of equally able test takers are systematically different between racial, ethnic, cultural etc. subgroups. Biased test scores may lead to unfair decisions or erroneous conclusions about individuals from particular subgroups. A test score is biased only if one or more of the test items are biased. A test item is biased if individuals with the same ability level from different subgroups have a different probability of a right response, i.e. the item has different difficulties in different subgroups. A test can be made fairer by deleting or improving the biased items.

Binet and Simon (1916; see Jensen 1980, p367) were already concerned with bias when they applied their test of general intelligence that was standardized on working class children to children of higher social status.

To assess bias some unbiased criterion measure of ability is needed. In some studies an external criterion for ability is at hand (e.g. Petersen and Novick, 1976). In most practical situations, however, no such external criterion is available and some criterion for ability internal to the test itself is used. Therefore most item bias detection techniques that are discussed in the literature use an internal criterion in some manner. The way in which this is done best distinguishes the methods from each other. Reviews are given by Osterlind (1983); Rudner Getson and Knight (1980); and Shepard, Camilli and Averill (1981). Handbooks on item
bias detection methods and research are Berk (1982) and Jensen (1980).

In the earlier item bias detection methods there is no explicit control of ability. For instance, in the analysis of covariance approach (Cardall & Coffman, 1965) transformed p-values are analyzed in a subgroup x items design. If there is a significant item by subgroup interaction, the item is considered biased. The analysis of variance assumption of equal cell variances is met by transforming the p-values by an arcsin transformation. Cleary and Hilton (1968), Hoepfner and Strickland (1972) and Jensen (1973) give further examples of this method.

The oldest and most popular item bias detection method is the transformed item difficulty method (Thurstone, 1925; Angoff, 1982; Angoff & Ford, 1973). It is conceptually very similar to the analysis of variance method, because it also studies the item x subgroup interaction of item difficulty. Angoff converted each p-value to a normal deviate (called delta's) by an inverse normal transformation. For all items delta values are compared between two subgroups by plotting these pairs of delta's in a bivariate graph. Angoff claims that the delta pairs for each item scatter around a straight line if the items are unbiased. If an item falls at some distance from the line this indicates an item x subgroup interaction. The item is then considered biased. Examples of practical application of this method are in Dorans (1982) and Donlon, Hicks and Wallmark (1980).

Both the analysis of variance method and the transformed item
difficulty method analyse subgroup x items interactions in item statistics on the subgroup level. Consequently, in these methods control for ability must be performed through correcting for differences between subgroup-level item statistics. This is logically unsatisfactory because, according to the definition of item bias, control for ability must be performed on the individual level. It is also unsatisfactory in practice. Hunter (1975) and Shepard Camilli and Williams (1985) show that when the items vary in difficulty and the distribution of ability is different in different subgroups, items x subgroups interactions can arise in perfectly unbiased tests.

A better way to control for ability is to use the raw score of the remaining test items as an estimate of ability. Item bias detection methods based on this idea, called chi-square methods, are proposed by Scheuneman (1979) and Mellenbergh (1982). Scheuneman uses data from an item response x subgroup x scoregroup contingency table to test the hypothesis that within each scoregroup the probabilities of a positive item response are the same for all subgroups. If the hypothesis is rejected the item are considered biased. Baker (1981) criticized Scheuneman's methods on the grounds that the distribution of the test statistic is unknown because Scheuneman used only the data from the positive responses. Camilli (1979) and Nungester (1977) (see Ironson 1982) proposed a test statistic based on both the correct and the incorrect item responses which is asymptotically distributed as a chi-square. Mellenbergh (1982) modified Scheuneman's method so that it fits in
the general theory of loglinear and logit models for contingency tables. This yields a parametric model describing different types of bias which can also be tested by chi-square statistics.

Chi-square methods can detect item bias very well. Rudner, Getson and Knight (1980) show that Scheuneman's method can detect item bias in simulated data where the responses are generated from a three parameter logistic model with different slope and locations in different groups. Van der Flier, Mellenbergh, Adêr and Wijn (1984) show that Mellenbergh's (1982) method works well in both empirical data and in simulated data generated by a certain three-parameter-normal ogive type model. Kok, Mellenbergh and van der Flier (1985) showed that the method also effectively detected experimentally induced item bias. Although in chi-square methods there is a better control for ability level than in the analysis of variance method and the transformed item difficulty method, taking ability as the number right score of the remaining items is rather informal and possibly inappropriate.

In item-response theory, ability is described by formal parameters. In these models the probability of an individual response to a certain item is explained by parameters describing the individual's ability and the item's difficulty. An item is considered biased if the item parameters are different for individuals with the same ability parameters from different subgroups.

Lord (1980) used Birnbaum's three parameter logistic model to detect biased items. The model contains three parameters: a lower
asymptote, a slope, and a location parameter of the item characteristic curve. The parameters are associated with guessing, discrimination, and difficulty, respectively. If one or more of the estimated item parameters differ significantly from subgroup to subgroup, the item is considered biased.

Muthen and Lehman (1985) uses multiple group factor analysis of dichotomous variables to test the invariance of the parameters of the two-parameter-normal-ogive model over subgroups.

Durovic (1975) as well as Wright, Mead and Draba (1975) use the Rasch model to detect item bias. For each item the mean squared differences between the observed responses and expected probabilities of a correct response were computed and compared between two subgroups.

In this paper the loglinear formulation of the Rasch model (Kelderman, 1984) is used to test the invariance of item parameters over subgroups. If the difficulty parameters vary from subgroup to subgroup the item is considered biased. Subgroup membership may be observed or unobserved. In some practical situations, items may be expected to be biased for certain subgroups of individuals, but it is not known a-priori to which subgroup each of the individuals belongs. For example, for an item in an examination the probability of a correct response may be larger for a group of individuals with specific educational experiences than for individuals without that experience, or for an item in a mastery test the probability of a correct response may be larger for a subgroup of individuals having a different study strategy or for a subgroup of individuals having
a different cognitive strategy to solve the item, etc. In these examples, information on the individuals' subgroup membership may be difficult to observe or, as in the last example, the test behavior itself may be the natural indicator of subgroup membership. In this paper a loglinear Rasch model is formulated where item difficulty may also vary over subgroups that are not observed.

In what follows, the choice of the Rasch model to detect item bias is discussed. Quasi-loglinear models are formulated for test data and the Rasch model is formulated as one of them. Some alternative models are described to test various aspects of item bias with respect to known subgroups. The use of these tests is illustrated on a set of test data from Kok (1982) where item bias was introduced experimentally. Finally, corresponding latent class models for item bias with respect to unknown subgroups are described, and the effects of this bias is discussed.

**Choice of model**

The Rasch model describes the probability $P(X_j = x_j | \alpha)$ that an individual with parameter $\alpha$ gives a response $X_j$ to item $j$ ($j=1,\ldots,k$), where $X_j$ can take values $x_j = 0,1$ for a wrong (0) or a right (1) response:

$$P(X_j = x_j | \alpha) = \frac{\exp(x_j(\alpha - \delta_j))}{1 + \exp(\alpha - \delta_j)} ,$$
where $\delta_j$ (j=1,...,k) is a single item parameter describing the
difficulty of item j. If this item parameter varies from subgroup
to subgroup, the item is considered biased. Although the Rasch
model is a rather simple model, its parsimony yields several
virtues in using it to detect item bias.

Firstly, unlike the Birnbaum model if in the Rasch model item A
has a larger item parameter value than item B, the probability of
getting a correct solution on item A is always smaller than the
probability of getting a correct solution on items B regardless of
the examinee's ability level. Consequently, if the data fit the
Rasch model, it makes sense to assert that item A is more difficult
than item B. The item parameter value may therefore justifiably be
interpreted as the item's difficulty (Rasch, 1966a), so that
differences in item parameters between different subgroups can be
interpreted as differences in item difficulty between subgroups.
The dependence on the subgroups of the item parameters can then be
analyzed to make a diagnosis of the item's flaws necessary to
improve the item.

Secondly, in item bias detection studies we are interested in
invariance of item parameters over subgroups and not in the
individual person parameter values within each subgroup. It is
therefore a desirable property of the Rasch model that the item
parameters are inferentially separable from the person parameters.
The Rasch model is an exponential family model wherein the simple
number right score $T = X_1 + ... + X_k$ is a sufficient statistic for
the person parameter $\alpha$. Assuming local independence of the item
responses for a given value of \( \alpha \) and after conditioning on the number right score taking the value \( t \), the joint probability \( P(X_1=x_1,\ldots,X_k=x_k|T=t) \) of the item responses \( Y \) \( \ldots \), \( X_k \) for a given score \( T=t \) becomes Rasch (1966b):

\[
(2) \quad P(X_1=x_1,\ldots,X_k=x_k|T=t) = \exp(-x_1\delta_1\ldots-x_k\delta_k) / \left( \prod_{k=1}^{k} \exp(-x_1\delta_1\ldots-x_k\delta_k) \right),
\]

By conditioning on the score, the nuisance parameter \( \alpha \) has vanished (Rasch 1966b). In this paper the invariance over subgroups \( i = 1,\ldots,m \) of the joint item response distributions for given values of \( T \)

\[
(3) \quad P_i(X_1=x_1,\ldots,X_k=x_k|T=t) = P(X_1=x_1,\ldots,X_k=x_k|T=t)
\]

is tested to study item bias. According to model (2) any deviation of this invariance must be explained by differences in item difficulty between the subgroups. Note from (2) that the use of the Rasch model to study item bias is both an observed score method and a latent-trait-model method.

Thirdly, the conditional Rasch model can be formulated (Kelderman, 1984) as a quasi-loglinear contingency table model (Fienberg, 1972; Bishop, Fienberg & Holland, 1975). Model (2) is then equivalent to the hypothesis that the item responses and the score are quasi independent (Goodman, 1968) in the incomplete score
x item 1 x ... x item k contingency table. Incomplete table methodology can be used to formulate several hypotheses about item bias by specifying alternative quasi-loglinear models that contain various subgroup dependent parameters. Testing the conditional Rasch model agains such models yields a test of the hypotheses.

Quasi-Loglinear-Models for the Incomplete Subgroup x Score x Item 1 x ... x Item k Table.

Let $f_{itx_1...x_k}$ be the number of individuals from subgroup $i$ ($i=1,...,m$) with number right score $T=t$ ($t=0,1,...,k$) and item scores $X_1=x_1$, ..., $X_k=x_k$ where $x_j = 1$ if item $j$ ($j=1,...,k$) is answered correctly and $x_j = 0$ if item $j$ is answered incorrectly. Since it is logically impossible to have a test score that is unequal to the number of correct item responses (excluding counting errors) the counts $f_{itx_1...x_k}$ are zero for $t \neq \sum x_i$. Table 1 shows the

| subgroup x score x item 1 x ... x item 3 contingency table for subgroup $i$. Dashes denote cells that are logically or structurally zero cell. Contingency tables with structurally zero cells are called incomplete contingency tables. |

Fienberg (1972; see also Bishop, Fienberg & Holland, 1975) presents a general theory for the statistical analysis of
Item Bias Detection

11

incomplete multiway contingency tables by quasi-loglinear models. We apply Fienberg's theory to the analysis of the subgroup x score x item 1 x ... x item k contingency table to detect item bias.

Let $m_{itx_1...x_k}$ be the expected counts for the table under some model. If $t \neq x_1 + ... + x_k$, the expected counts are again structurally zero. If $t = x_1 + ... + x_k$, the expected counts are structurally nonzero and these counts are explained by a quasi-loglinear model. The saturated or fully specified model for the table is:

$$
\ln m_{itx_1...x_k} =
$$

$$
u + u_1(i) + u_2(t) + u_3(x_1) + ... + u_{(k+2)}(x_k)
$$

$$
+ u_{12}(it) + u_{13}(ix_1) + ... + u_{(k+1)(k+2)}(x_{k-1}x_k)
$$

$$
+ u_{123}(itx_1) + ... + u_{123...(k+2)}(itx_1...x_k)
$$

for $i = 1, ..., m; x_1 = 0, 1; ...; x_k = 0, 1; t = x_1 + ... + x_k$,

where $\ln$ is the natural logarithm. Model (4) has constraints:

$$
u_1(+) = u_2(+) = ... = u_{(k+2)}(+) = u_{12}(+t) = u_{12}(i+) =
$$

$$
u_13(+x_1) = u_13(i+) = = u_{(k+1)(k+2)}(+x_k) =
$$

$$
u_{(k+1)(k+2)}(x_{k-1}+) = ... = u_{123}(+tx_1) = u_{123}(i+x_1) =
$$

$$
u_{123}(it+) = ... = u_{123...(k+2)}(+tx_1...x_k) =
$$

$$
u_{123...(k+2)}(i+x_1...x_k) =
$$

$$
u_{123...(k+2)}(itx_1...x_{k-1}+) = 0.
$$
The u-terms in model (4) describe main effects and interaction effects of subgroup i, score t and item responses $x_1, ..., x_k$. The u-terms in expression (5) denote sums of parameters that occur in model (4) where a plus sign replacing an index indicates that the summation is over the replaced index. The constraints (5), however, are not sufficient to ensure that all parameters in model (4) are estimable. Additional constraints must be imposed to obtain a unique solution of the model parameters. These constraints will be discussed later.

Restrictive quasi-loglinear models are defined by setting u-terms in (4) equal to zero. The only models considered here will be hierarchical, i.e. whenever a particular u-term is set to zero, all its higher order relatives must also be set to zero.

**The Rasch Model as a Quasi-Loglinear Model.**

A restrictive quasi-loglinear model is

\[
\ln m_{itx_1...x_k} = u + u_1(i) + u_2(t) \\
+ u_{12}(it) + u_3(x_1) + ... + u_{k+2}(x_k)
\]

with the constraints

\[
\begin{align*}
  u_1(+) &= u_2(+) = u_{12}(+) = u_{12}(i+) = \cdots = u_3(+) = ... = u_{k+2}(+) = 0
\end{align*}
\]
Model (6) can be obtained from the saturated quasi-loglinear model (4) by setting all interactions with and between item responses equal to zero.

If the subgroup and score are taken as fixed variables and the item responses are considered as random variables, model (6) is equivalent to the conditional Rasch model. In that case $m_{itx_1...x_k}$ is the conditional expected frequency of the response $X_1=x_1$, ..., $X_k=x_k$ for given subgroup $i$ and score $t$. The conditional probability of response $X_1=x_1$, ..., $X_k=x_k$ for $i$ and $t$ can then be obtained from (6) by

$$P_i(X_1=x_1, \ldots, X_k=x_k | T=t) = \frac{m_{itx_1...x_k}}{\sum_{x_1} \ldots \sum_{x_k} m_{itx_1...x_k}}$$

$$= \frac{\exp(u_3(x_1)+\ldots+u_{k+2}(x_k))}{\sum_{x_1} \ldots \sum_{x_k} \exp(u_3(x_1)+\ldots+u_{k+2}(x_k)) \cdot x_1+\ldots+x_k=t}$$

Except for a reparametrization, model (8) is equivalent to model (2). In model (2) the effect $-x_j \delta_j$ of a response $X_j=x_j$ on item $j$ is $-\delta_j$ for a correct response ($X_j=1$) and zero for an incorrect response ($X_j=0$), whereas in model (8) the effect of a correct response is $u_{j+2}(1)$ and the effect of an incorrect response is $u_{j+2}(0)$, where $u_{j+2}(0) = -u_{j+2}(1)$ by the constraints (7). Model (8) can be parametrized in the same way as model (2) if $u_{j+2}(1)$ is added to each parameter $u_{j+2}(x_j)$ so that the new parameter $u_{j+2}(x_j)$
+ u_{j+2}(1) becomes u_{j+2}(0) + u_{j+2}(1) = 0 with an incorrect response and 2u_{j+2}(1) with a correct response. This can be done by multiplying both numerator and denominator by

$$\exp(u_2(1)+...+u_{k+2}(1)),$$

so that model (8) becomes model (2) with

$$-x_j \delta_j = u_{j+2}(x_j) + u_{j+2}(1) = x_j(2u_{j+2}(1)),$$

for all $j = 1, ..., k$; i.e. $\delta_j = 2u_{j+2}(0)$. This shows that the Rasch model is equivalent to the quasi-loglinear model (6).

In model (6) there is an obvious overparameterization because of the linear dependence of the item responses and the score: adding a constraint c to each of the item parameters $u_{j+2}(1)$ $(j=1,...,k)$ and subtracting c from $u_{j+2}(0)$ $(j=1,...,k)$ to satisfy the constraints (7) is equivalent to adding $t.c - (k-t).c = (2t-k).c$ to $u_2(t)$. This indeterminacy can be removed from model (2) by putting one linear constraint on the item parameters, e.g. by setting $u_{k+2}(x_k)$ equal to zero.

We now describe less restrictive quasi-loglinear models that can be used to detect item bias.

Quasi-Loglinear Models to Detect Item Bias.

To study item bias in a particular set of data, quasi loglinear
models may be set up that contain subgroup-dependent item parameters in addition to the parameters of the Rasch model (Rasch, 1960). The fit of these models can be compared by a likelihood ratio test with the fit of more restrictive models to test the significance of each of the subgroup-dependent item parameters. If a test yields a significant result, the item is biased. The subgroup-dependent item parameters each describe a particular type of item bias.

To detect the simplest type of bias, e.g. in item one, the model

\[
\ln m_{xt1 \ldots x_k} = u + u_1(i) + u_2(t) + u_{12}(it) +
\]

\[
+ u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{13}(ix_1),
\]

with the usual constraints (5), is compared with the loglinear Rasch model (6) to test the null hypothesis that the interaction between the subgroup and the response to item one, \(u_{13}(ix_1)\) is zero. If the test is significant, it may be concluded that \(u_{13}(ix_1)\) is not zero so that the difficulty of item one varies from subgroup to subgroup. The parameter \(u_{13}(ix_1)\) is the change of item easyness in subgroup \(i\) and \(u_3(x_1) + u_{13}(ix_1)\) is the easyness of item \(x_1\) in subgroup \(i\).

In model (9) a \(u\)-term is specified to test item bias for only one item. Obviously similar \(u\)-terms can be specified for two or more items if necessary. For example, comparing the loglinear Rasch model with the model:
(10) \[ \ln m_{i}x_{1}\ldots x_{k} = u + u_1(i) + u_2(t) + u_{12}(it) + u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{13}(ix_1) + u_{14}(ix_2), \]

yields a simultaneous statistical test for bias in both item one and item two.

An item may be more difficult in one subgroup than another, because the item introduces some specific difficulty, e.g. reading ability, in which the members of one subgroup are generally more proficient than the members of another. If the ability to solve this difficulty varies from individual to individual within each of the subgroups and if there are two items in the test that both introduce the same difficulty we may expect these items to show an interaction that is not explained by the original latent trait.

This interaction may be investigated using the model:

(11) \[ \ln m_{i}x_{1}\ldots x_{k} = u + u_1(i) + u_2(t) + u_{12}(it) + u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{13}(ix_1) + u_{14}(ix_2) + u_{34}(x_1x_2) + u_{134}(ix_1x_2) \]

which contains two u-terms, \( u_{34}(x_1x_2) \) and \( u_{134}(ix_1x_2) \) describing an interaction between item one and two. If \( u_{134}(ix_1x_2) \) is zero but \( u_{34}(x_1x_2) \) is not zero, there is a simple interaction between both items that is the same in all subgroups. If \( u_{134}(ix_1x_2) \) is not zero, the interaction is different from subgroup to subgroup. This may, for example, be the case if reading ability does introduce common variance in one subgroup, does not introduce any
variance in another subgroup, because the individuals in that subgroup are all of superior reading ability.

Comparing model (11) with the loglinear Rasch model (6) yields a test for the hypothesis that all subgroup-dependent item parameters in model (11) are simultaneously zero. If the test is significant, it may be concluded that one or more of these parameters are not zero. Comparing model (11) with model (10) yields a test for the item interaction terms alone. To test both item interaction terms \( u_{34}(x_1x_2) \) and \( u_{134}(x_1x_2) \) separately, an intermediate submodel must be defined that contains \( u_{34}(x_1x_1) \) but not \( u_{134}(x_1x_2) \).

---

Table 2 lists all relevant models (a. through e.) containing subgroup-dependent item parameters for the case of two items. Table 3 summarizes which models in Table 2 must be compared to test specific subgroup-dependent item parameters. Hypothesis 3 shows which models must be compared to test \( u_{34}(x_1x_2) \) and \( u_{134}(x_1x_2) \) respectively.

Hypothesis 1-4 in Table 3 refer to what Mellenbergh (1982) has called 'uniform' item bias. It means that the bias is constant within each subgroup. With 'nonuniform' item bias (Mellenbergh, 1982) the bias of in each subgroup is dependent on the individuals ability level. Nonuniform bias may be studied with quasi-loglinear models containing item parameters that depend both on the subgroup and the score.
Table 2 shows a series of models (f. through m.) with subgroup- and score-dependent item parameters. Since quasi-loglinear models are hierarchical, each model with a subgroup x score x item(s) interaction term must contain the corresponding subgroup x item(s) interaction term. In Table 2 all models f through m contain a submodel from models a through e, which is indicated by its letter for brevity. Table 3 shows which of these models must be compared to obtain a statistical test that is sensitive to a specific type of nonuniform item bias. Note that these tests concentrate only on the nonuniformity of the bias and not on the uniform part of the bias. Therefore, if these tests are not significant, items may still be uniformly biased.

Hypothesis 5 in Table 3 concerns the simplest type of nonuniformity in item bias. If model g and f (Table 2) differ significantly, it can be concluded that the subgroup x score x item interaction \( u_{123}(ity) \) is not zero. This nonuniformity in item bias may be expected, for example, if the difficulty of an item varies from subgroup to subgroup for low ability individuals only, which is the case if an item involves a specific skill that is not mastered by the low ability individuals of only one of the subgroups.

Hypothesis 6 (Table 3) concerns this hypothesis for two items simultaneously, whereas hypothesis 7 and 8 address the question whether item interaction is nonuniform \( u_{234}(tx_{1x2}) \neq 0 \) or whether subgroup differences in item interaction are nonuniform \( u_{1234}(ito_{1x2}) \neq 0 \). This may be called nonuniform common item bias,
where the amount of item bias that two items have in common depends on ability level. This type of item bias may occur, for example, if in only one subgroup two items introduce a common difficulty for low ability individuals but do not introduce a common difficulty for high ability subjects.

In most of the models in Table 2, the constraints are not sufficient to ensure identifiability of the model parameters. For example, the parameter $u_{23}(tx_1)$ with $t=0$ and $x_1=1$ or $t=0$ and $x_1=0$ cannot be estimated because it corresponds to structurally zero cells only. A convenient way to determine the number of estimable parameters is to determine the rank of the information matrix, which should be equal to the number of estimable parameters for a given set of data (cf. McHugh, 1956; Goodman, 1974). Baker and Welder (1978, sec. 4.3) describe a weighted least-squares algorithm for the analysis of contingency tables, which estimates the parameters in a sequential fashion. If a parameter is linearly dependent on the preceding parameters, or if there are no observations to estimate it from, the parameter is removed from the model, thus the information matrix is of full rank.

**Estimation and Testing**

The kernel of the log likelihood is
Item Bias Detection

(12) \[ x = \ln p_1 p_2 \cdots p_k (m_{itx_1 \ldots x_k}) \]

\[ = \sum_{i} \sum_{t} f_{itx_1 \ldots x_k} \ln m_{itx_1 \ldots x_k} \]

Inserting a loglinear model for \( \ln m_{itx_1 \ldots x_k} \) this log likelihood yields a sum of products of model parameters (e.g. \( u_3(x_1) \)) with the corresponding sufficient marginal counts (e.g. \( f_{++x_1+...+} \)). For example, using the loglinear Rasch model (6) in (12) gives

(13) \[ x(\text{Rasch}) = f_{+...+} + \sum f_{i+...+} u_1(i) + \sum f_{+t...+} u_2(t) \]

\[ + \sum f_{itx_1...x_k+} u_12(it) + \sum f_{++x_1...+} u_3(x_1) \ldots \]

\[ + \sum f_{+...+x_k} u_{k+2}(x_k) \]

where a plus sign replacing an index denotes summation over that index.

Log likelihoods of larger models (e.g. Model 9) may be obtained by adding terms (e.g. \( \sum f_{1+x_1+...+u_{13}(x_1)} \)) to (13). If one model - say model \( M \) - is a special case of another model - say model \( M^* \) - model \( M^* \) may tested against model \( M \) by \(-2 \) times the natural logarithm of the likelihood ratio of both models, or equivalently, by \(-2 \) times the difference in log likelihood of both models

(14) \[ G^2(M;M^*) = -2(\lambda(M)-\lambda(M^*)) \]
Under the assumption of model $M$, $G^2$ is asymptotically distributed as chi-square with degrees of freedom equal to the number of estimable parameters of both models (Bishop, Fienberg & Holland, 1973, p. 525; Rao, 1965, p. 351).

An overall goodness at fit test for model $M$ is obtained by testing it against the saturated model $M^*$ where in the expected cell counts ($m$) in (12) are set equal to the observed cell counts ($f$).

For example the Rasch model (6) is a special case of model (9). Model (9) has all parameters of the Rasch model but adds the term $u_{13}(ix_1)$. Testing model (6) against model (9) is a test for the hypothesis $u_{13}(ix_1) = 0$. If the parameter estimates of both model (6) and (9) are known, the likelihood-ratio statistic $G^2(M;M^*)$ can be calculated easily from the sufficient marginal sums corresponding to the parameters.

Maximum-likelihood estimates of the model parameters can be obtained by setting the observed marginal counts corresponding to each of the parameters equal to the corresponding expected marginal counts and solving the resulting system of equations for the parameters (Haberman, 1979, p. 448). For example, for the Rasch model the maximum-likelihood equations are

\begin{equation}
fit+...+ = m_{it+...+} \quad \text{and} \quad f_+...+x_j+...+ = m_+...+x_j+...+
\end{equation}

for $i = 1, \ldots, m; \ t = 0, \ldots, k$

and $x_j = 0,1; \ j = 1, \ldots, k$. 
In general, for quasi-loglinear models, the maximum-likelihood equations yield no direct solution of the model parameters. The equations must be solved iteratively. Algorithms to solve the maximum-likelihood equations for quasi-loglinear models have been described by Goodman and Fay (1974: ECTA) and Baker and Nelder (1978: GLIM). Kelderman (1983) describes a generalisation to multiway tables of an algorithm by Goodman (1964, 1968) that calculates the parameters of quasi-loglinear models without setting up the entire incomplete contingency table, so that memory space required can be modest if the number of items is not small.

An Example.

Kok (1982) studied item bias in multiplication items by experimentally varying the test takers' skill in bias factors that can be expected to be operating in differently formulated test items. In this section, some of these data are reanalyzed to illustrate the use of quasi-loglinear models for the detection of item bias.

Table 4

Table 4 shows the contents of six multiplication items. In item 1 through 4 the numbers are written out in Dutch and in item 5 and 6 Roman numerals are used. The subjects were 286 Dutch undergraduates of which 144 randomly selected individuals received
a short training in Roman numerals. It can be expected that the Roman items are biased.

---

**Table 5**

In Table 5 for each item the values of the likelihood ratio test and the degrees of freedom are shown for both uniform (hypothesis 1, Table 3) and nonuniform bias (hypothesis 5, Table 3). From Table 5 it is seen that item 5 and item 6 are uniformly biased. There is no nonuniform bias in this set of data. Since both item 5 and 6 are written in Roman numerals, we would expect both items to be biased by a common bias factor. To test this, hypothesis 3 and 4 of Table 3 are tested. Neither showed a significant result ($G^2(c,d)=0.2$, $DF=1$; $G^2(d,e)=1.4$, $DF=1$). We can, therefore, conclude that item 5 and item 6 are uniformly biased but not that the bias factors of both items are the same.

The model with both item 5 and 6 uniformly biased (i.e. (10)) gives a good fit to the data ($G^2=106.8$, $DF=107$). The estimates for the item parameters $u_4(x_2)$ through $u_8(x_6)$ are 0.36, 0.40, -0.51, 0.05 and 0.03 respectively for $x=1$; where the first item parameter is fixed at zero. The subgroup $x$ item response parameters $u_{17}(x_5)$ and $u_{18}(x_6)$ for $x=1$ and $i=1$, the group that received a training in Roman numerals, are 0.21 and .27 respectively. That is, the items are much easier for the group that received the training in Roman numerals.
When subgroup membership is unobserved the subgroup variable becomes a latent variable. The models to detect item bias then become latent-class models. For example, if the latent classes are denoted by $\omega(\omega=1,\ldots,m)$, the latent class version of model (9) becomes

$$
\ln m_{\omega, x_1, \ldots, x_k} = u + u_1(\omega) + u_2(t) + u_{12}(\omega t) + u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{13}(\omega x_1) 
$$

$\omega = 1, \ldots, m; x_1=0,1; \ldots; x_k=0,1; t=x_1+\ldots+x_k$; with the usual constraints 5.

Model (16) describes a Rasch model in each latent class $\omega$, where the difficulty of item 1 may be different in each latent class. The parameter $u_{13}(\omega x_1)$ describes the differences in item difficulty between the latent classes. If this parameter is not zero, item 1 is biased with respect to the latent classes.

Latent-class models have been introduced by Lazarsfeld (1950; Lazarsfeld & Henri, 1968; Goodman, 1978). At first, latent-class models assumed local independence within each latent class. Goodman (1975) introduced latent-class models where the observed variables form an incomplete-contingency table assuming quasi independence within each latent class. Finally, Haberman (1979, ch. 10) formulates a latent-class model for an incomplete table where the model is not necessarily an independence model. The model can be
any identifiable loglinear model containing unobserved categorical variables. Model (16) is a special case of Haberman's general latent class model where item 1 may have a different difficulty in each of m latent classes, where the number m of latent classes is specified by the investigator. Not all latent class versions of the models to detect item bias (Table 2) make sense, since parameters involving the latent-class variable may be wholly absorbed by lower order parameters involving observed categorical variables only. These latent-class parameters are then redundant and not identifiable. This holds true for most models for nonuniform-item bias.

For example, consider the latent class version of model g Table 2:

\[ \ln \frac{m_{\omega t x_1 \ldots x_k}}{m_{x_1 \ldots x_k}} = u + u_1(\omega) + u_2(t) + u_{12}(\omega t) + u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{13}(\omega x_1) + u_{23}(t x_1) + u_{123}(\omega x_1) \]

The expected value of the observed counts \((t, x_1, \ldots, x_k)\) are then

\[ m_{t x_1 \ldots x_k} = \exp \left( u + u_2(t) + u_3(x_1) + \ldots + u_{k+2}(x_k) + u_{23}(tx_1) + g_1(tx_1) \right) \]

where

\[ g_1(tx_1) = \ln \sum_{\omega} \exp \left( u_1(\omega) + u_{12}(\omega t) + u_{13}(\omega x_1) + u_{123}(\omega x_1) \right) \]
Now $g(tx_1)$ can be completely absorbed by $u$, $u_2(t)$, $u_3(x_l)$ and $u_{23}(tx_1)$ to obtain new parameters using the following reparametrisation:

\[ u^* = u + \bar{g}_1(++) , \]

\[ u^*_2(t) = u_2(t) + \bar{g}_1(t+) - \bar{g}_1(++) , \]

\[ u^*_3(x_l) = u_3(x_l) + \bar{g}_1(+x_l) - \bar{g}_1(++) , \]

\[ u^*_{23}(tx_1) = u_{23}(tx_1) + g_1(tx_1) - \bar{g}_1(t+) - \bar{g}_1(+x_l) + \bar{g}(++) , \]

where the notation $\bar{g}_1(t+)$ is used to denote an average over the subscripts replaced by a plus sign. This shows that the latent-class terms in model (17) are redundant. Consequently there is no latent-class version of test 5 of table 3. A similar argument holds for test 8; the latent class term $u_{1234}(tx_1x_2)$ is adsorbed by its lower order relatives involving observed variables $t, x_1$ and $x_2$.

In the latent-class models for detecting uniform bias the latent-class parameters are not adsorbed. For example latent-class version of the model used to test one-item uniform bias (16) yields the expected values of the observed counts:

\[
(18a) \quad m_{tx_1...x_k} = \exp \{ u + u_2(t) + u_3(x_l) + ... + u_{k+2}(x_k) + g_2(tx_1) \} ,
\]

where
Item Bias Detection

(18b) \[ g_2(t x_1) = \ln \sum_{\omega} \exp\{u_1(\omega) + u_{12}(\omega t) + u_{13}(\omega x_1)\}, \]

so that if we set

(19a) \[ u^* = u + \bar{g}_2(+) \]

\[ u_2^*(t) = u_2(t) + \bar{g}_2(t+) - \bar{g}_2(+) \]

\[ u_3^*(x_1) = u_3(x_1) + \bar{g}_2(x_1) - \bar{g}_2(+) \]

\[ u_{23}^*(t x_1) = g_2(t x_1) - \bar{g}_2(t+) - \bar{g}_2(x_1) + \bar{g}(+) \]

the model

(19b) \[ \ln m_{x_1 \ldots x_k} = u^* + u_2^*(t) + u_3^*(x_1) + u_4^*(x_2) + \ldots + u_{k+2}^*(x_k) + u_{23}^*(t x_1) \]

satisfies the usual constraints (5).

In model (18) the term \( g_2(t x_1) \) is not absorbed by lower order terms. The corresponding term \( u_{23}^*(t x_1) \) describes a specific interaction between the test score and item 1. From (18b) it can be seen that this parameter arises both from differences in item difficulty over latent classes \( u_{13}(\omega x_1) \) as well as differences in testscore distribution in over latent classes \( u_{12}(\omega t) \). If one of these effects are zero, the \( g_2(t x_1) \) becomes constant over one index, so that from (19a) \( u_{23}^*(t x_1) \) becomes zero. For example
if \( u_{13}(\omega_{x}) \) becomes zero \( g_{2}(tx_{1}) \) does no longer depend on \( x_{1} \) so that \( g_{2}(tx_{1}) = g_{2}(tx_{1}^{i}) \) for all \( x_{1}^{i} \neq x_{1} \). Consequently \( g_{2}(+x) = \overline{g}_{2}(++) \) and \( g_{2}(tx_{1}) = \overline{g}_{2}(tx_{1}) \) for all \( x \) so that \( u_{23}^{*}(tx_{1}) \) becomes zero.

If \( u_{23}^{*}(tx_{1}) \) is nonzero, the item character curve of item one deviates from the ICC predicted by the Rasch model. This means that deviations of the ICC's of a certain item may be explained as item bias of that item with respect to unknown subgroups. Introducing latent classes may provide an alternative to introducing additional item parameters as in the two and three parameter logistic test model.

The latent-class versions of the remaining models for detecting uniform bias (model c-e. Table 2) also contain non-redundant latent-class terms. Writing the models for the expected values of the counts, the latent class parameters of model c-e similarly produce terms \( u_{234}(tx_{1}x_{2}) \) and lower order relative terms that are not already specified in the observed part of the model. This means that score dependent item interaction may result from differences in item difficulty or differences in item interaction between latent subgroups.

Methods for the estimation and testing of latent-class-quasi-loglinear models differ from those for ordinary quasi-loglinear models. Since latent class membership is unobserved, the frequencies \( f_{\omega x_{1}...x_{k}} \) are not known. Consequently, the maximum-likelihood equations (e.g. \( f_{\omega x_{1}+} = m_{\omega x_{1}+} \) for parameters involving latent classes \( \omega \) (e.g. \( u_{13}(\omega x) \)) cannot be solved because the
frequencies are unknown. Haberman (1979, ch. 10), however, gives the a rule for the derivation of maximum likelihood estimates in latent-class models from the known frequencies $f_{tx_1...x_k}$. It says that: "The same maximum-likelihood equations apply as in the ordinary case in which all frequency counts are directly observed, except that the unobserved counts are replaced by their estimated conditional expected values given the observed marginal totals".

Under some loglinear model M (e.g. Model (16)), these estimates are

\[
(20) \quad f_{\omega t x_1 ... x_k} = E_M(f_{\omega t x_1 ... x_k} | f_{tx_1...x_k})
\]

\[
= (\tilde{m}_{\omega t x_1 ... x_k} / \tilde{m}_{tx_1 ... x_k}) f_{tx_1 ... x_k}
\]

\[
t = x_1 + ... + x_k
\]

For model (16) the likelihood equations would then become

\[
(21) \quad f_{\omega t + ... + t} = \tilde{m}_{\omega t + ... + t} \quad f_{+ ... + x_k} = \tilde{m}_{+ ... + x_k}
\]

The estimated counts $\tilde{f}$ are obtained from (20) where the $\tilde{m}$ are described by model (16). A scoring algorithm to solve these equations has been described by Haberman (1979, p. 556). An alternative way to solve these equations, is by using the E-M algorithm (Dempster Laird & Rubin, 1977) with (20) as the expecta-
tion step and (21) as the maximization step.

Discussion

In this paper an item bias detection method is proposed that uses a Rasch latent trait as an internal criterion for ability. Latent trait parameters of the model are removed from the model by conditioning on the number right score and the quasi loglinear formulation of the model is extended with parameters that describe different types of item bias. The general theory of (quasi-) loglinear models is used to obtain maximum likelihood parameter estimates and likelihood ratio tests.

Using Haberman's (1979) latent class generalisation of quasi-loglinear models it is shown that even if subgroup membership is unknown it is still possible to determine whether different individuals with the same ability level have different probabilities of a correct response on a certain item.

It is also shown that nonzero item bias parameters with respect to latent classes can alternatively be modelled as parameters that describe deviations of item difficulty in different scoregroups. This means that the item characteristic curve of that item deviates from item characteristic curve predicted by the Raschmodel. Consequently, at least part of the structure in the item responses that is explained by slope parameters in the Birnbaum model may be explained as item bias. Since item bias can be interpreted as multidimensionality, item specific slope parameters may partly be
explained as multidimensionality the item response.

The models presented in this paper have two parts: one part contains parameters describing item bias, the other part contains parameters for the Rasch measurement model. It may be objected that the Rasch model is too restrictive a model for the measurement part and that a less restrictive, possibly multidimensional model, is preferred. Two remarks in favour of the Rasch model are in order here.

Firstly, as was seen before, there is a trade-off between the complexity of the item bias part of the model and the measurement part of the model. A more complex measurement model, e.g. a model with slope parameters for the item characteristic curve, may hinder the identification of certain types of item bias. Therefore if identification of item bias is the objective and nothing is known about the right (possibly multidimensional) measurement model, a simple measurement model is to be preferred. Unlike many other item bias detection methods a check of the adequacy of the item bias detection model is available because the overall fit of the model can be tested by a chi-square test.

Secondly, in general it is more desirable to construct unidimensional than multidimensional test items because the interpretation of the responses is less ambiguous. Even if a multidimensional test or item bank is needed to cover a certain content domain it is better to construct a number of homogeneous subsets of items. In that case the models presented in this paper can be applied to short subtests. Obviously, it is more probable
that short subtests fit the Rasch model than that long subtest do. For one item the Rasch model is trivially true.

Item bias detection methods using an internal ability criterion, assume that a good measure of this criterion is available, i.e. that the item used to measure this criterion fits the measurement model. If that is not the case, particularly if one or more of these items are biased themselves, the results may be erroneous. Marco (Lord, 1980, p. 228) proposed a procedure to purify a test of biased items. The total test is analyzed, items that appear to be biased are removed and the remaining items are used as an internal ability criterion to test the bias of all the testitems one by one. Although this procedure does not escape the inherent circularity of the problem it should suffice if not too many items are biased. This procedure can also be used with the test presented in this paper where in the first phase only one item-uniform bias is tested and in the second cycle the set of unbiased items is combined with pairs of possibly biased items to use the diagnostic tests presented in this paper.

Finally it should be remarked that the item bias part of the models may be more elaborate. The models in this paper contain parameters that indicate deviations due to item bias. Kok and Mellenbergh (1985) goes further and formulates models that describe the actual processes involved in the genesis of item bias more precisely. Our models may be used to give directions as to which of Kok's models may be appropriate.
