Abstract

Raman spectra of zinc phthalocyanine monolayers, adsorbed on gold and on glassy carbon surfaces (electrodes), are presented. These spectra have been recorded with the electrodes inside and outside an electrochemical cell filled with an aqueous electrolyte. A confocal Raman microspectrometer was used. It was demonstrated that, because this spectrometer uses low laser intensities, no damage of the monolayer occurred. The results show that the interaction of the phthalocyanine molecule with gold differs from that with glassy carbon. Because the laser excitation wavelength (660 nm) coincides with a UV-visible absorption band (Q band), a strong resonance-enhanced Raman spectrum was obtained. No signs of surface enhancement (surface-enhanced Raman scattering) effects were detected.

INTRODUCTION

Transition metal phthalocyanines, especially those with iron and cobalt, are interesting catalysts for the electroreduction of molecular oxygen [1-5]. The redox properties of these compounds adsorbed on carbon supports have been reported [2-6]. It has been shown that the interaction between adsorbate and support influences the electrocatalytic activity [3,6], i.e. different carbon supports result in
a different catalytic activity of the adsorbate. To study this support–adsorbate interaction, Raman scattering may be used.

Raman spectra of phthalocyanine (sub)monolayers adsorbed on noble metal electrodes have already been reported [7–9], but here we will present at the same time spectra of zinc phthalocyanine (ZnPc) adsorbed on gold and on glassy carbon electrodes that are placed in an aqueous electrolyte. These spectra were obtained by means of a recently developed confocal Raman microspectrometer (CRM) [10,11]. ZnPc itself has no electrocatalytic properties but it was chosen as a model compound to demonstrate that Raman spectra of adsorbed phthalocyanines can be obtained irrespective of the support material. The redox behaviour of ZnPc is relatively simple as oxidation occurs only with the organic ligand while alteration of the oxidation state of the central zinc ion is not likely. Moreover, we do not expect that Raman spectra of adsorbed ZnPc are affected by axial ligands such as oxygen, either inside or outside the electrochemical cell. Also, the UV–visible spectroscopic data of ZnPc in its reduced and oxidized forms have been tabulated [12–14]. On the basis of these data it will be shown that to obtain Raman spectra of ZnPc monolayers one has to ensure that resonance enhancement takes place. Finally we will show that interaction of ZnPc with the support is visible in the Raman spectrum.

**EXPERIMENTAL**

ZnPc was obtained commercially and utilized without further purification.

The ZnPc monolayer was obtained by immersing the support in a dilute solution of ZnPc in concentrated sulphuric acid. The electrode was immersed in water (millipore super Q) and treated in an ultrasonic bath for 5 min. All supports were cleaned rigorously in concentrated sulphuric acid and boiled twice in (super Q) water. The amount of adsorbed ZnPc on the electrodes was calculated from the results of voltammetric and coulometric measurements. These experiments were carried out in a standard three-electrode cell with 0.1 M HClO₄ as the supporting electrolyte and a mercury/mercury sulphate/K₂SO₄(sat) electrode (MSE) as the reference electrode.

Raman spectra of ZnPc monolayers on gold and glassy carbon electrodes were recorded both inside (in situ) and outside (ex situ) an electrochemical cell. The electrolyte, a nitrogen-saturated 0.1 M HClO₄ solution, was pumped through the cell. All potentials quoted are measured against the MSE. A schematic representation of the experimental set-up for the in situ measurements is given in Fig. 1.

The CRM has been described in detail in ref. 10. Spectral resolution was 6–7 cm⁻¹. A Spectra Physics model 375B dye laser (660 nm), operated with the laser dye 4-dicyanomethylene-2-methyl-6-[(p-dimethylamino)styryl]-4H-pyran, was used for excitation. Laser power at the sample was 2 mW in all experiments. A ×63/0.17 microscope objective (numerical aperture, 0.85) was used to focus the light on the sample and to collect the scattered light. The irradiated spot on the sample has a diameter less than 1 μm. The confocal detection of scattered light
restricted the effective measuring volume to roughly 1 μm³. The Raman signal from the adsorbed layer passes through a pinhole in the image plane of the objective (Fig. 1) but background signals (from the solution and window of the electrochemical cell) are suppressed. The spectra of ZnPc on glassy carbon have been corrected for residual background signals. Wavenumber calibrations were made on the basis of the spectrum of indene, recorded at the same settings of the CRM as in the presented experiments. Peak positions are accurate within 2 cm⁻¹.

RESULTS AND DISCUSSION

Cyclic voltammetry was used to check the thickness of the adsorbed ZnPc layers (Figs. 2 and 3). From these experiments it follows that the oxidation reaction is reversible. Because only one electron is involved in the oxidation of ZnPc [13] the number of adsorbed molecules can be calculated from the amount of charge that is transferred in the anodic or cathodic peak. Under the assumption of a perfect smooth surface, typical values for the number of ZnPc molecules on gold and glassy carbon were $3.5 \times 10^{13}$ cm⁻² and $2 \times 10^{13}$ cm⁻² respectively. From X-ray data [15] and with the approximation that a phthalocyanine molecule is a square
with an area of 200 Å² one calculates coverages of 70% and 40% for the gold and the glassy carbon electrodes respectively. We take these results as a proof that the adsorbed layers are (sub)monolayers indeed.

Fig. 3. The cyclic voltammogram of the ZnPc adsorbed on a gold electrode in 0.1 M HClO₄. Scan rate, 80 mV s⁻¹.
We verified that damage of the adsorbed layer by the laser beam does not occur. In one experiment we kept the laser beam focused for 8 min at one point on the glassy carbon electrode surface. From Fig. 4 it can be seen that the ZnPc spectrum remained unaltered in shape and intensity.

Figures 5 and 6 show Raman spectra of adsorbed ZnPc on glassy carbon and gold electrodes at the open loop potential (−30 mV and −100 mV for glassy carbon and gold respectively) and at 350 mV (MSE). At the latter potential most of the ZnPc molecules exist, according to Figs. 2 and 3, in their oxidized form. Also at this potential the Raman spectrum collapses. Switching the potential back to the original open loop value restores the original spectrum in shape and intensity. Two observations can be made: first, the oxidation of the ZnPc layer is reversible and the oxidized form remains adsorbed at the electrode surface and, second, only the neutral form contributes to the Raman spectrum. The second observation can be explained by the resonance character of the spectrum as follows. The 660 nm laser line coincides with the broad absorption band (Q band) of neutral ZnPc, and resonance enhancement can be expected. On oxidation this Q band shifts considerably to shorter wavelengths (550 nm) [13,14] and resonance enhancement no longer occurs. To exclude the possibility that surface-enhanced Raman scattering (SERS) effects play a role, we also recorded the spectrum of ZnPc adsorbed on glass. As shown in Fig. 7, the intensities of the Raman spectra of ZnPc adsorbed

on glass, gold and on glassy carbon are of the same magnitude. Because of this and because of the fact that SERS effects on glass are not possible, only resonance enhancement is operative.

Analysis of the spectra of Fig. 7 also reveals differences that we attribute to differences in adsorbate–support interaction. Although peak positions are the same for all supports studied, peak intensities do vary. The peaks at 1335 and 1506 cm\(^{-1}\), the pyrrole stretching modes [16], are stronger in the case of the glassy carbon support than in the case of gold and glass supports. Comparison of the ex situ and in situ spectra of ZnPc on gold reveals an intensity increase for the pyrrole stretching modes in the latter case (Figs. 7(c) and 6). No such differences are observed with glassy carbon (Figs. 7(a) and 5). Support-specific differences are also found in the band around 1430 cm\(^{-1}\) (Figs. 5 and 6). The latter modes have been assigned to C–N vibrations [16]. These observations suggest that the interaction with the support takes place via the nitrogen atoms of ZnPc. In fact this conclusion has also been drawn by Coowar et al. [6] who studied the long-term electrochemical stability of adsorbates of iron naphthalocyanines on several different carbon supports and found that the stability of the adsorbate paralleled the surface concentration of acidic groups.
