The change in conductivity of Fe and Ti implanted rf-sputtered layers of yttria-stabilized zirconia (YSZ) was studied as a function of the temperature (400-800 °C) and oxygen partial pressure. In an oxidized state and in the temperature range of 400-600 °C, the conductivity of the Fe implanted YSZ film (15 keV, 8 × 10¹⁶ at.cm⁻²) was dominated by the n-type electronic conductivity of a thin Fe₂O₃ layer with an estimated thickness of less than 2 nm on top of the YSZ thin film. Due to the incorporation of a part of the implanted Fe atoms in the yttria-stabilized zirconia lattice, the ionic conductivity was somewhat decreased. In a reducing atmosphere this electronic conduction was no longer observed. In an oxidized state, the conductivity of the YSZ film was not influenced by the implantation of Ti (15 keV, 8 × 10¹⁶ at.cm⁻²). After reduction in a H₂ atmosphere, an increase in the conductivity of the sputtered film with 2-3 orders of magnitude was observed. This has been ascribed to the presence of nonstoichiometric TiO₂₋ₓ, which is an n-type semiconductor.

1. Introduction

Yttria-stabilized zirconia (YSZ) is an important oxygen ion conducting solid electrolyte [1]. Both ceramic bulk materials and thin films deposited by sputtering [2,3] or chemical vapour deposition [4,5], are used in applications like oxygen sensors, oxygen pumps and fuel cells [6]. The exchange of oxygen between the gas and the electrolyte can be described with the following overall reaction:

\[ \text{O}_2 (\text{gas}) + 2 \text{V}^{\cdot\cdot} + 4 e^- = 2 \text{O}^\cdot\cdot \]  (1)

where, in Kröger–Vink notation, O^\cdot\cdot is a normal O²⁻ ion in the yttria-stabilized zirconia lattice and, V^{\cdot\cdot} an oxygen-ion vacancy. When noble metal electrodes are used, the exchange of oxygen between the gas phase and the solid electrolyte is geometrically limited to regions near to the three phase boundary between the oxygen gas, solid electrolyte and electronic conductor.

Mixed conducting oxides, which exhibit as high an ionic and electronic conductivity as possible, have advantages in comparison with the presently used electronic conductors [7-9]. With good mixed conducting oxides, the electrochemical exchange of oxygen would occur over the entire electrode–gas interfacial area in which both oxygen ions and electrons are mobile. The large increase in the reaction area will significantly decrease the electrode polarization and hence the efficiency losses at the electrode, \text{O}_2 (\text{gas})/\text{solid electrolyte} interface.

Mixed conducting zirconia-based electrodes [10,11] have advantages in comparison with other mixed conducting oxides in terms of the chemical and mechanical stability of the electrode-electrolyte interface. As both the chemical composition and thermal expansion are similar to the electrolyte itself it is expected that the integrity of the electrode-electrolyte interface can easily be maintained.

The electrode materials should also show good catalytic activity for the electrochemical oxidation of H₂ and other fuel gases, if used as anode, and for the electrochemical reduction of O₂ if used as cathode. The costs of the electrode material should be low and the lifetime as long as possible.

Previous publications [12-14] reported on efforts to develop mixed conducting electrode materials by doping yttria-stabilized zirconia with transition metal
oxides [12–14]. In this paper the mixed conductivity of the implanted layers is studied. The layers were prepared through implantation of the corresponding transition metal ions into stabilized zirconia thin films, which were deposited on insulating Al$_2$O$_3$ substrates. This procedure was followed in order to increase the contribution of the ion implanted part of the yttria-stabilized zirconia substrate to the total conductivity of the ion implanted sample. If a bulk ceramic yttria-stabilized zirconia substrate is used it is possible that the ionic conductivity of the not implanted part of this substrate would have dominated the total conductivity of the sample.

As ion implantation is a non-equilibrium process, it has the capability of producing materials with compositions and microstructures unattainable by conventional ceramic techniques. In this study, for example, concentrations of the implanted ions are obtained which are far beyond the limit corresponding to the equilibrium solid solubility level. High concentrations of the transition metal oxide may be necessary in order to obtain the desired effects.

2. Experimental

Yttria-stabilized zirconia thin films (65-108 nm) were deposited on polished polycrystalline alumina substrates by rf-sputtering in a Leybold-Hereaus Z 500 apparatus. The cathode was made of finely powdered yttria-stabilized zirconia (composition: (ZrO$_2$)$_{0.83}$(YO$_{1.5}$)$_{0.17}$, called 'ZY17') using polyvinylalcohol as binder [15]. The plasma atmosphere was a mixture of argon and oxygen (82 and 18%, respectively) and the total pressure was stabilized at 1.5×10$^{-2}$ mbar. All the deposits were made at a constant discharge power of 540 W and with a bias voltage of 120 V. A deposition rate of 1.6 Å/s was obtained. After deposition the samples were annealed at 900°C in air during one hour.

The Fe or Ti doping of the layer was accomplished by ion implantation. The ion implantations were performed at room temperature in a vacuum of 4×10$^{-7}$ Torr. The YSZ films were implanted perpendicular to the sample surface at a beam current density of 2 μA cm$^{-2}$ using the isotope separator of the Laboratory for General Physics (LAN) of the State University of Groningen. For the hot cathode ion source FeCl$_2$·4H$_2$O (Merck, p.a.) was used as feed material for Fe implantations. For the Ti implantation heated TiO$_2$ (BDH Chemicals Ltd.) was chlorinated in situ with carbon tetrachloride.

The compositions and thickness of the stabilized zirconia thin films were analyzed by Rutherford Backscattering (RBS) using a 2 or 3 MeV ⁴He ion beam. All measurements were carried out with a scattering angle (θ) of 165° in the laboratory frame of reference, and with the analyzing beam perpendicular to the sample's surface. The mean composition of the Fe and Ti implanted films in terms of cation concentration ratio's was determined from the area under the appropriate signals, taking into account the corresponding differential scattering cross sections of the cations. The stopping cross section of the compound YSZ target was calculated from the atomic composition according to Bragg's rule [16], enabling the RBS energy scale to be translated into a depth scale (at.cm$^{-2}$). The at.cm$^{-2}$ depth scale was recalculated in nm by assuming that the atomic density was the same as that for crystalline yttria-stabilized zirconia. Corrections were applied for the limited energy resolution of the surface barrier detector (26 keV (FWHM)), and for the range straggling (i.e. statistical broadening in the energy distribution due to multiple interactions) of the scattered ions [16].

Four rectangular shaped platinum electrodes were painted on the surface of the film, as shown in fig. 1. The platinum electrodes were sintered in air at 850°C during one hour. Four platinum point electrodes were spring loaded on these painted elec-
trodes. All samples were oxidized in air at 850°C prior to the four-point probe conductivity measurements, which were performed in a N2 (P02=1×10⁻⁵ atm) or H2 (P02=1×10⁻² atm) atmosphere in the temperature range of 400–800°C. The current between the two outer electrodes was delivered by the internal power supply of a Keithley 617 electrometer, which also measured the potential difference between the two inner potential probes. The current was measured with a Keithley 616 electrometer. The resistance was determined from the slope of the steady-state current versus potential plot.

3. Results

3.1. Composition analysis

Fig. 2 shows RBS spectra observed on yttria-stabilized zirconia thin films, both before and after the implantation of Fe or Ti (15 keV, 8×10¹⁶ at.cm⁻²). The vertical arrows indicate the energy of ⁴He ions scattered from surface atoms of Hf, Zr+Y, Fe, Ti, Al and O, respectively. Hf was present as an impurity (2 wt.%) in the sputtering target of yttria-stabilized zirconia from which the stabilized-zirconia thin film was deposited. Under the experimental conditions, the energy edges of ⁴He ions scattered from surface atoms of Y or Zr could not be resolved. The signal of ⁴He scattered from Al is shifted towards lower energy in comparison with the energy edge of ⁴He scattered from surface atoms of Al because of the energy loss in the yttria-stabilized zirconia layer.

As can be seen in figs. 2b and 2c the depth profile of the implanted Fe and Ti ions extends over approximately the whole thickness of the YSZ sputtered film. This is somewhat unexpected as RBS measurements [17,18] from Fe and Ti implanted bulk ceramic discs (15 keV, 8×10¹⁶ at.cm⁻²) revealed and Fe and Ti depth profile extending to a
Table 1
Composition of yttria-stabilized zirconia films and their final thickness after the Fe and Ti implantation, as used for the conductivity measurements. \(N_V\), \(N_{Zr}\), \(N_{Fe}\) and \(N_{Ti}\) represent the total number of Y, Zr, Fe or Ti atoms in the layer, as determined by Rutherford Backscattering (RBS). The ratio \((N_V/(N_V+N_{Zr})) = 0.17\) resulted from X-ray fluorescence (XRF).

depth of 20 nm, with a maximum \(Fe/(Fe+Zr+Y)\) and \(Ti/(Ti+Zr+Y)\) ratio of 0.5 and 0.7, respectively. This Fe and Ti depth profile would extend to half of the thickness of the YSZ sputtered layer used in this study. The discrepancy may result from the fact that the RBS spectra of the implanted sputtered YSZ films have been measured after measuring their conductivity. Diffusion of the implanted ions into deeper layers of the sputtered YSZ film during the conductivity measurements might have occurred, giving rise to a broader Fe and Ti depth distribution. The composition and thickness of the sputtered films which were used for conductivity measurements are shown in table 1.

3.2. Electrical conductivity measurements

The conductivity of a non-implanted yttria-stabilized zirconia thin film as a function of the temperature is shown in fig. 3 (Arrhenius diagram). In the same figure it is compared with the conductivity of an yttria-stabilized zirconia single crystal of the same composition \(((ZrO_2)_{0.83}(YO_{1.5})_{0.17})\), as determined by Badwal [19]. The conductivity values of the sputtered film are one order of magnitude lower than the single crystal values. In the Arrhenius diagram of the conductivity of the sputtered film a decrease in the activation energy is observed from \((121 \pm 4)\) kJ mol\(^{-1}\) at 800\(^\circ\)C to \((76 \pm 4)\) kJ mol\(^{-1}\) at 400\(^\circ\)C. The conductivity of this yttria stabilized zirconia film is the same in a H\(_2\) or N\(_2\) atmosphere.

The implantation of the stabilized zirconia film with 15 keV Fe up to a dose of \(8 \times 10^{16}\) at.cm\(^{-2}\) results in a small decrease of the conductivity of the stabilized zirconia layer in the temperature range of 600–800\(^\circ\)C, as shown in fig. 4. The activation energy increases from \((121 \pm 4)\) kJ mol\(^{-1}\) for the non-implanted film towards \((152 \pm 5)\) kJ mol\(^{-1}\) for the Fe implanted film. In the temperature range of 400–600\(^\circ\)C the conductivity is approximately equal to the
Fig. 4. Conductivity of yttria-stabilized zirconia thin film after the implantation of 15 keV Fe up to a dose of $8 \times 10^{16}$ at. cm$^{-2}$ and subsequent oxidation in air at 850°C, as measured in an atmosphere of either N$_2$ ($P_{O_2} = 1 \times 10^{-5}$ atm) or H$_2$ ($P_{O_2} = 1 \times 10^{-23}$ atm) gas. The conductivity data for the non-implanted film are shown for comparison: ($\square$) non-implanted, N$_2$ atmosphere; (○) 15 keV Fe, $8 \times 10^{16}$ at. cm$^{-2}$, N$_2$ atmosphere; (+) 15 keV Fe, $8 \times 10^{16}$ at. cm$^{-2}$, H$_2$ atmosphere.

The conductivity of the non-implanted film if measured in a N$_2$ atmosphere. The conductivity of the Fe doped film in the temperature range of 400–600°C decreases, however, considerably if the sample is reduced at 800°C in a H$_2$ atmosphere. After reduction in the H$_2$ atmosphere, a linear Arrhenius diagram is observed with an activation energy of $(152 \pm 5)$ kJ mol$^{-1}$ in the whole temperature range of 400–800°C.

The implantation of the stabilized zirconia film with 50 keV Fe up to a dose of $8 \times 10^{16}$ at. cm$^{-2}$ results also in a decrease in the conductivity of the stabilized zirconia film, as shown in fig. 5. Both in a H$_2$ and N$_2$ atmosphere a linear Arrhenius diagram is observed in the whole temperature range of 400–800°C with an activation energy of $(152 \pm 5)$ kJ mol$^{-1}$. This activation energy resembles the activation energy of the conductivity of the 15 keV Fe implanted film after reduction in the H$_2$ atmosphere.

The implantation of the stabilized zirconia film with 15 keV Ti up to a dose of $8 \times 10^{16}$ at. cm$^{-2}$ does not result in a significant change in the conductivity if measured in a N$_2$ atmosphere, as shown in fig. 6. However, the reduction of the Ti implanted film in H$_2$ at 800°C results in an increase of the conductivity with 2–3 orders of magnitude. The activation energy changes from $(121 \pm 4)$ kJ mol$^{-1}$ for the non-implanted film towards $(29 \pm 1)$ kJ mol$^{-1}$ for the Ti implanted sample after reduction in a H$_2$ atmosphere.

4. Discussion

The conductivity of the sample, as determined with
Fig. 6. Conductivity of yttria-stabilized zirconia thin film after the implantation of 15 keV Ti up to a dose of $8 \times 10^{16}$ at.cm$^{-2}$ and subsequent oxidation in air to 850°C, as measured in an atmosphere of either $N_2$ ($P_{O_2} = 1 \times 10^{-5}$ atm) or $H_2$ ($P_{O_2} = 1 \times 10^{-25}$ atm) gas. The conductivity data for the non-implanted film are shown for comparison: (□) non-implanted, $N_2$ atmosphere; (○) 15 keV Ti, $8 \times 10^{16}$ at. cm$^{-2}$, $N_2$ atmosphere; (+) 15 keV Ti, $8 \times 10^{16}$ at. cm$^{-2}$, $H_2$ atmosphere.

The four platinum probes, is the sum of both the ionic and electronic conductivity [20]. The two types of conductivity can be discriminated from each other by their oxygen partial pressure dependence. The ionic conductivity of yttria-stabilized zirconia is independent of the oxygen partial pressure, as the oxygen vacancy concentration is fixed by the amount of yttria. The electronic conductivity is, however, strongly dependent on the oxygen partial pressure. The total conductivity may be dominated by one of the two types of conductivity.

The conductivity of the rf-sputtered film of YSZ is independent of the oxygen partial pressure ($N_2$ ($P_{O_2} = 1 \times 10^{-5}$ atm) versus $H_2$ ($P_{O_2} = 10^{-25}$ atm)). In this study, this is taken as an indication that the measured conductivity is essentially ionic. Other investigators [2,3] proved this more rigorously by measuring the ionic transport number. Values close to unity were obtained for both calcia- and yttria-stabilized zirconia thin films.

The conductivity of the rf-sputtered film of YSZ is one order of magnitude smaller than the conductivity of a single crystal with the same composition. Part of this difference can be explained with the surface roughness of the underlying polycrystalline $A_l_2O_3$ substrate. By polishing, a mean surface roughness was obtained of about 50 nm, which is close to the thickness of the sputtered films (65–108 nm) used in this study. The texture of the sputtered film was not studied, but a poor crystallinity, grain boundaries and porosity will all contribute to a decreased conductivity of the sputtered thin film in comparison with the YSZ single crystal. The change in activation energy of $E_{act} = (76 \pm 4)$ kJ/mol (400–600°C) to $E_{act} = (121 \pm 4)$ kJ/mol (600–800°C) is in the opposite direction as the change in ionic conductivity of polycrystalline YSZ bulk materials [21]. No explanation for this effect can be given so far.

The implantation of 15 keV Fe up to a dose of $8 \times 10^{16}$ at.cm$^{-2}$ results after oxidation in air in a stabilized zirconia layer with approximately the same conductivity as the non-implanted layer. This result implies that the increased conductivity of a stabilized zirconia film after the implantation of Fe up to a dose of $8 \times 10^{16}$ at.cm$^{-2}$, as observed by Scholten [22], could not be reproduced. This discrepancy might result from a different thermal history of the sample. As observed in RBS spectra of the Fe implanted film, some redistribution of the implanted Fe atoms towards deeper layers takes place during the conductivity measurements. The thickness of the YSZ films used in the conductivity measurements of our study (60 nm) was somewhat smaller than the film thickness used by Scholten (100 nm). So changes in the conductivity of the Fe implanted film would have been more easily observed in our study. But also the measurement technique has been improved. The small current (only several nA) has been measured more accurately. The conductivity was no longer measured during heating of the sample but after a thermal equilibration of a few hours. In the present study the conductivity of the sample has been determined from the slope of the steady state current versus potential plot. Scholten [22] determined the conductivity from a single measurement of the cur-
rent and the corresponding potential, neglecting a possible offset voltage. More careful analysis showed the offset voltage to be too large to be ignored.

The conductivity of the Fe implanted film is, however, different from the conductivity of the non-implanted film in respect to its oxygen partial pressure dependence. The conductivity of the Fe implanted film in the temperature range of 400–600°C significantly decreases after reduction in a H₂ atmosphere. This was not observed for the non-implanted film.

In view of the results obtained previously, the outermost surface of this Fe implanted stabilized zirconia layer will mainly consist of Fe₂O₃ with an approximate thickness of 2 nm [17,18]. Pure Fe₂O₃ is an n-type semiconductor [23] below 800°C and its conductivity is determined by electronic charge carriers. Its electronic conductivity is somewhat larger than the ionic conductivity of stabilized zirconia, as indicated in fig. 3. Due to the limited extent of this Fe₂O₃ layer, it will contribute only little to the total conductivity of the stabilized zirconia film. But especially in the low temperature region, it may dominate over the ionic conductivity.

The reduction of this Fe implanted sample in a H₂ atmosphere will result in a reduction of the Fe₂O₃ layer towards metallic Fe. The microstructure of this layer is not known but in a similar experiment performed on Fe implanted Al₂O₃ it was shown that metallic Fe particles were formed which were not connected [24]. In the “as-implanted” state of Fe implanted YSZ metallic Fe precipitates have been identified by Scholten [22] and Burggraaf et al. [14], using Conversion Electron Mössbauer Spectroscopy. Hence the conducting surface layer of Fe₂O₃ is lost. If the precipitates are not connected this will result in a decrease of the conductivity of the Fe implanted film.

Fe³⁺ can be substitutionally incorporated for Zr⁴⁺ in the stabilized zirconia lattice up to 7 mol% Fe₂O₃ [22], which corresponds to a cation fraction of 0.15. Precipitation of small Fe₂O₃ particles occurs when the concentration corresponding to this solubility level is exceeded. The mean concentration of Fe in the sputtered film, as shown in table 1, exceeded the Fe concentration corresponding to its solubility level (cation fraction of 0.15). Thus part of the implanted Fe can be expected to form Fe₂O₃ precipitates in an oxidizing atmosphere. The dissolution of Fe₂O₃ in the YSZ lattice results in oxygen vacancies in the oxygen sublattice according to the following incorporation reaction (Kröger–Vink notation):

$$\text{Fe}_2\text{O}_3 = 2\text{Fe}^{2+}_\text{Zr} + 3\text{O}_\text{Zr}^\text{c} + \text{V}_\text{O}^\text{c}.$$  \hspace{1cm} (2)

Such an increase in oxygen vacancy concentration may in principle result in an increase of the ionic conductivity of the stabilized zirconia film. This is, however, only true in the case of low dopant concentrations. When the dopant concentration increases an optimum is reached whereafter the conductivity starts to decrease [25]. At the same time an increase in the activation energy is observed. Due to the doping with Y₂O₃, an oxygen vacancy concentration was present in the stabilized zirconia film close to this optimum in the ionic conductivity. Hence, further doping with other three-valent cations will result in a decrease of the conductivity and an increase in the activation energy. Both the reduction of the Fe₂O₃ layer towards not interconnected metallic Fe precipitates and the optimum which is present in the ionic conductivity of YSZ as a function of the dopant concentration can explain the decrease in conductivity in the range of 400–600°C in the Arrhenius-diagram of fig. 4, followed by a simultaneous increase of the activation energy.

The implantation of 50 keV Fe up to a dose of $8 \times 10^{16}$ at.cm⁻² results in a gaussian depth profile under the surface of the stabilized zirconia film with a mean projected range of 19 nm and range straggling of 8.5 nm. The stabilized zirconia film is more uniformly doped due to the larger mean projected range and range straggling of the implanted Fe atoms in comparison with the 15 keV Fe implantation. No surface layer of Fe₂O₃ is expected to be present. Both in a N₂ and H₂ atmosphere a decrease in the conductivity in combination with an increase in the activation energy is observed in comparison with the non-implanted YSZ layer. This can be explained with the same argument as discussed for the case of the 15 keV Fe implanted layer. Once again a dopant concentration is reached beyond the optimum in the curve of ionic conductivity versus dopant concentration.

In view of the results obtained previously [17,18], the outermost surface layer of the Ti implanted sample will mainly consist of TiO₂. Just below this surface layer, the stabilized zirconia layer is doped with
Ti up to a depth of 18 nm and with a maximum cation fraction of Ti of about 0.70. TiO$_2$ can be substitutionally incorporated for Zr in the stabilized zirconia lattice up to 15 mol% [10,26]. Precipitation of ZrTiO$_4$ was observed in ceramic yttria-stabilized zirconia samples if the TiO$_2$ concentration exceeded the concentration corresponding to this solubility level [26], but not yet for Ti implanted YSZ. The mean concentration of Ti in the sputtered film, as shown in table I, exceeds the Ti concentration corresponding to the solubility level of TiO$_2$ in YSZ. From the conductivity measurements it can, however, be concluded that neither the incorporation of TiO$_2$, nor the expected precipitation of ZrTiO$_4$ did apparently result in a change in the conductivity of the YSZ layer if measured in a N$_2$ atmosphere.

The reduction of the Ti implanted layer resulted in a remarkable increase in the conductivity with 2-3 orders of magnitude. This may result from the formation of a layer of nonstoichiometric TiO$_{2-x}$, which is an n-type semiconductor [27]. The conductivity of TiO$_{2-x}$ has been indicated in fig. 3 for comparison. A large increase in mainly electronic conductivity can indeed be expected. It may also result from the reduction of that part of Ti that is incorporated substitutionally for Zr in the YSZ lattice. In this view, the Ti$^{4+}$ states, which act as electron acceptors when empty, are filled upon reduction, i.e. the forming of Ti$^{3+}$. At sufficiently high concentrations of these (acceptor-)states, an impurity band can form, resulting in an increase of the conductivity of the Ti implanted YSZ film. Furthermore, when Ti is incorporated for Zr in the YSZ lattice this may result in a decrease of the bandgap. This effect is presently under investigation [28]. Previously this effect has been observed in the system SrZrO$_3$ [29]. In strongly reduced Ti-doped YSZ the Ti$^{3+}$ states may then act as electron donors, increasing the concentration of conduction band electrons and hence increasing the electronic conductivity.

5. Conclusions

Rf-sputtering of yttria-stabilized zirconia (YSZ) resulted in thin films with an ionic conductivity which has one order of magnitude lower than the conductivity of YSZ in a single crystal form. This is ascribed to the microstructure of the sputtered film.

The implantation of 15 keV or 50 keV Fe up to a dose of $8 \times 10^{16}$ at.cm$^{-2}$, and subsequent oxidation of the implanted layer in air results in a decrease in ionic conductivity and an increase in its activation energy. This has been explained by the incorporation of part of the implanted Fe atoms as Fe$^{3+}$ on a Zr$^{4+}$ lattice position in the YSZ lattice.

The conductivity of the 15 keV Fe implanted layer is oxygen partial pressure dependent in the temperature range of 400-600°C. This can be ascribed to the presence of an Fe$_2$O$_3$ layer (thickness < 2 nm) on top of the sputtered YSZ thin film. In this low temperature region, the n-type electronic conductivity of Fe$_2$O$_3$ dominates the electronic conductivity of the underlying YSZ sputtered film.

The implantation of 15 keV Ti up to a dose of $8 \times 10^{16}$ at.cm$^{-2}$ does not result in a significant change in the total conductivity of the YSZ thin film if measured in an oxidized state. After reduction in a H$_2$ atmosphere at 800°C, an increase in conductivity is observed with 2-3 orders of magnitude. This large increase in conductivity can be ascribed to the n-type conductivity of nonstoichiometric TiO$_{2-x}$.
