The ultimate regime of thermal convection, the so-called Kraichnan regime [R. H. Kraichnan, Phys. Fluids 5, 1374 (1962)], hitherto has been elusive. Here numerical evidence for that regime is presented by performing simulations of the bulk of turbulence only, eliminating the thermal and kinetic boundary layers and replacing them with periodic boundary conditions.

DOI: 10.1103/PhysRevLett.90.034502

Thermally driven turbulence is of tremendous importance in oceanography, geophysics, meteorology, astrophysics, or process technology. If the flow is confined to a box heated from below and cooled from above, the setup is called Rayleigh-Bénard (RB) convection. It is one of the classical problems in fluid dynamics [1,2]. The control parameters are the dimensionless temperature difference between bottom and top (called Rayleigh number Ra), the ratio between kinematic viscosity \( \nu \) and heat diffusivity \( \kappa \) (called Prandtl number \( \text{Pr} \)), and the aspect ratio of the cell. The system answers with some heat transfer from the bottom to the top (called Nusselt number \( \text{Nu} \) in dimensionless form) and the degree of turbulence in the cell (expressed in terms of the Reynolds number \( \text{Re} \)).

All classical experiments on this system show (effective) power law dependences with \( \text{Nu} \sim Ra^{0.25} \) up to \( \text{Nu} \sim Ra^{0.33} \). However, for very large Ra, Kraichnan [3] has predicted an ultimate scaling law \( \text{Nu} \sim Ra^{1/2} \). In this ultimate state the heat flux and the turbulent velocity are expected to be independent of the viscosity and heat diffusivity. Indeed, for a system with infinite aspect ratio a mathematically strict upper bound \( \text{Nu} \leq 0.167Ra^{1/2} - 1 \) could be found [4].

Hitherto, this ultimate state of thermal convection remained elusive [5], in spite of tremendous efforts to find it. Niemela et al. [6] measured up to \( Ra \approx 10^{18} \) in helium gas close to the critical point (\( \text{Pr} \approx 1 \)), still finding an effective power law \( \text{Nu} \sim Ra^{0.31} \). Glazier et al. [7] measured up to \( Ra \approx 10^{11} \) in mercury (\( \text{Pr} \approx 0.025 \)), finding \( \text{Nu} \sim Ra^{0.28} \). The only evidence for a transition (at \( Ra \approx 10^{11} \)) towards the ultimate regime has been claimed by Chavanne et al. [8,9], but Niemela and Sreenivasan [10] argue that those data would be consistent with \( \text{Nu} \sim Ra^{1/3} \). In summary, it is therefore not clear (i) whether in today’s experiments the Rayleigh number is only too small for the ultimate state, or (ii) whether it does not exist at all.

However, it is crucial to know which of these two alternatives is the correct one: (i) for practical reasons, in view of the above-mentioned applications of thermal convection in geophysics, industry, etc., as upscaling from lab-scale models does not work if there is a transition to a new state of turbulence; (ii) for fundamental reasons, as is a “central dogma in turbulence” [5] that its effects become independent of viscosity and diffusivity for large enough Reynolds (or here Rayleigh) numbers [11]. Indeed, also within Grossmann and Lohse’s unifying theory on thermal convection [12,13] the Kraichnan or ultimate regime follows, once the thermal and kinetic boundary layers either break down due to their expected instability at large Ra or hardly contribute to the global kinetic and thermal dissipation [14]. According to Ref. [13] the breakdown of the laminar kinetic boundary layer should happen at \( Ra \approx 10^{14} \) for \( \text{Pr} = 1 \) and at \( Ra \approx 10^{12} \) for \( \text{Pr} = 0.025 \) for an aspect ratio \( \Gamma = 1 \) cell; Niemela and Sreenivasan [10] find similar values. Then the total kinetic dissipation rate \( \epsilon_k \) equals the bulk kinetic dissipation \( \epsilon_{k,\text{bulk}} \) and the total thermal dissipation rate \( \epsilon_{\theta} \) equals the bulk thermal dissipation \( \epsilon_{\theta,\text{bulk}} \) and the Kraichnan or ultimate regime with

\[
\text{Nu} \sim Ra^{1/2}Pr^{1/2} \tag{1}
\]

and

\[
\text{Re} \sim Ra^{1/2}Pr^{-1/2} \tag{2}
\]

results [12].

From the above it follows that an artificial destruction of the boundary layers should enhance the ultimate regime. Indeed, by performing Rayleigh-Bénard convection experiments in a cell with rough top and bottom walls, Roche et al. [15] find evidence for the onset of the Kraichnan regime.

Here we follow another approach: We perform numerical simulation of the bulk of turbulence only, eliminating the thermal and kinetic boundary layers and replacing them with periodic boundary conditions [16]. Then the Kraichnan regime should follow immediately. The thermal bulk turbulence is forced by a mean temperature profile \(-\Delta/L\), where \( L \) is the periodicity length and \( \Delta \) the temperature difference on that length scale. The temperature fluctuations \( \theta \) then obey the advection equation

\[

\[ \partial_t \theta + u_i \partial_i \theta = \kappa \partial_i \partial_j \theta + u_3 \frac{\Delta}{L}. \]  

The velocity field \( u_i(x, t) \) obeys the standard Boussinesq equation,

\[ \partial_t u_i + u_j \partial_j u_i = -\partial_i p + \nu \partial_j^2 u_i + \beta g \delta_{i3} \theta. \]

\( \beta \) is the thermal expansion coefficient, \( g \) gravity, and \( p \) the pressure. \( \text{Ra} \) and \( \text{Pr} \) are defined as usual as \( \text{Ra} = \beta g \Delta L^3 / (\nu \kappa) \) and \( \text{Pr} = \nu / \kappa \), respectively. The Prandtl number is defined as usual as \( \text{Nu} = (u_3 \theta) L / (\kappa \Delta) - \partial_3 (\partial_3 \theta) \Lambda L / \Delta \).

The Reynolds number is defined with the rms mean velocity fluctuation \( u' \), i.e., \( \text{Re} = u'L / \nu \). A similar simulation has earlier been performed by Borue and Orszag [17]. The focus of that work was on scaling properties and spectra, and thus hyperviscosity has been employed.

From Eqs. (3) and (4) one can derive by volume averaging and assuming statistically stationarity the exact [18] relations \( \epsilon_\theta = \kappa L^{-2} \Delta^2 \text{Nu} \) and \( \epsilon_u = \nu^3 L^{-4} \text{Nu} \text{Ra} \text{Pr}^{-2} \). As in Refs. [12] we estimate \( \epsilon_u,_{\text{bulk}} \sim u'^3 / L \) and \( \epsilon_\theta,_{\text{bulk}} \sim \Delta^2 / L \), and the Kraichnan regime (1) and (2) results. Note that \( L \) is the relevant length scale for these estimates as for the Bolgiano length scale it holds \( l_B \approx L \).

This Kraichnan scaling is indeed seen in our numerical simulations of Eqs. (3) and (4). We run four different \( \text{Ra} \) numbers \( \text{Ra} = 8.64 \times 10^5 \) (for 160 large eddy turnovers), \( \text{Ra} = 2.21 \times 10^6 \) (for 60), \( \text{Ra} = 4.51 \times 10^6 \) (for 180), and \( \text{Ra} = 1.38 \times 10^7 \) (for 334), and average over space and time to obtain \( \text{Nu} \) and \( \text{Re} \) [19]. The Ra scaling is consistent with Eqs. (1) and (2); see Fig. 1. To our knowledge it is the first realization of the ultimate regime of thermal convection. It is remarkable that it is realized in spite of the relatively low \( \text{Ra} \) numbers of the simulations. The reason is that the boundary layers have been eliminated and the simulations focus on the bulk. Because of the lack of boundary layers and the more efficient driving, the Reynolds numbers achieved here are much larger than they would be in the standard Rayleigh-Bénard case. Vice versa, the required Rayleigh numbers to achieve the same degree of turbulence for the standard Rayleigh-Bénard case as here are much higher. For example, to achieve \( \text{Re} = 4996 \) (here for \( \text{Ra} = 1.38 \times 10^7 \)) one needs a Rayleigh number of \( \text{Ra} = 7.2 \times 10^8 \) in the standard case [20].

In conclusion, from the above alternatives the first one is favorable: Once Ra is so large that the laminar kinetic boundary layer breaks down, the ultimate regime of thermal convection, which has been so elusive in experiment, should finally show up. Obviously, the ultimate proof for the existence of this regime can come only from experiment.

[14] Regimes $IV_l$, $IV'$, and $II_l$ in the phase diagram Fig. 2 of Ref. [13].
[18] Note that for the standard RB case the corresponding second relation reads $\epsilon_u = \nu^2 L^{-4}(\text{Nu} - 1)\text{RaPr}^{-2}$.
[19] These relatively long averaging times are required to achieve statistical stationarity. As already pointed out in Ref. [17], they have to be longer than in the standard Rayleigh-Bénard case, due to the huge fluctuations of large scale quantities. These resemble the ones found for homogeneous shear flow [see, e.g., A. Pumir and B. I. Shraiman, Phys. Rev. Lett. 75, 3114 (1995)], to which our system indeed is comparable in some sense.
