Reactive hyperaemia, which occurs after a period of arterial occlusion is the result of an autoregulatory mechanism, involving local factors and autonomic nerve system control. To determine this autoregulatory mechanism in cutaneous blood flow in premature newborns we measured the cutaneous reactive hyperaemia response after a 1 min occlusion, using a diode laser Doppler flowmeter applied to the skin. Twenty-four infants with a gestational age ranging from 25 to 37 weeks and a postnatal age of 0.3 to 72 days were studied. The reactive hyperaemia response is described by the parameters maximal cutaneous blood flow ($V_{\text{max}}$), the time to reach maximal flow ($t_{\text{max}}$), the time taken for blood flow to return to baseline following $V_{\text{max}}$ ($t_{\text{end}}$) and the % increase in cutaneous blood flow above preocclusional level (overshoot). A cutaneous reactive hyperaemia response could be elicited in all infants. Following occlusion the $V_{\text{max}}$ was $2640 \pm 1050$ mV (mean ± SD), the $t_{\text{max}}$ was $7.6 \pm 3.9$ sec (mean ± SD), the $t_{\text{end}}$ was $35.6 \pm 14.6$ sec (mean ± SD) and the overshoot was $74.6 \pm 34$ % (mean ± SD). A negative correlation was found between hematocrit and $t_{\text{max}}$ ($r = -0.62$, $p < 0.01$). No influence of postconceptional age, postnatal age, skin and rectal temperature, incubator temperature, weight, and transcutaneous oxygen tension on the reactive hyperaemia parameters could be found. We conclude that reactive hyperaemia of cutaneous blood flow can be elicited in premature newborn infants irrespective of postconceptional age, and that the hematocrit is inversely related to the time to reach maximal flow after occlusion. Key words: reactive hyperaemia, premature newborn, laser Doppler, cutaneous blood flow.

Reactive hyperaemia is the increase in blood flow in a part of the body, where circulation is restored after a period of occlusion (1). Following an occlusion, vasodilatation occurs, which is probably the result of a combination of physical and chemical factors, namely changes in transmural pressure (2) and accumulation of a dilator substance (3). Previous studies on reactive hyperaemia in newborn premature infants have shown conflicting results. Some authors (4, 5) found a decreased reactive hyperaemia response and a lower baseline flow with increasing postconceptional age, whereas others (6, 7) reported an increasing reactive hyperaemia response and a higher baseline flow with increasing postconceptional age. Moreover, the earlier studies on reactive hyperaemia in newborn premature infants were done with venous occlusion plethysmography of the limbs, which reflects the blood flow of both skin and muscles (4, 6, 8, 9, 10, 11). This method does not discriminate between cutaneous and muscular blood flow. The present study was undertaken to determine if postocclusive reactive hyperaemia of cutaneous blood flow is present in premature newborns and if we could find changes in this response with increasing
gestational, postconceptional and postnatal age. Therefore the reactive hyperaemia response of cutaneous blood flow of the forearm after a short term occlusion was determined in newborn infants of different postconceptional age, using a diode laser Doppler flowmeter applied to the skin.

MATERIALS AND METHODS
Twenty-four newborn infants of different postconceptional age were studied. Birthweight and gestational age varied from 0.80 to 3.77 kg (mean 1.53) and from 25.0 to 37.0 weeks (mean 30.5) respectively. Postconceptional age at time of the study ranged from 28.0 to 37.0 weeks (mean 32.5). Postnatal age varied from 0.3 to 72 days (mean 14.9). The infants were studied in incubators at their neutral environmental temperature according to Sauer et al. (12). None of the infants had cardiovascular disease. Infants receiving any medication that could possibly affect blood vessel tone were not included in the study. All infants were on a continuous feeding regimen by gavage and/or parenteral nutrition. Behavioral state was determined by observation and by assessment of respiration and heart rate according to the criteria of Prechtl & O'Brien (13). Active sleep was seen during 146 of the 157 analysed occlusions.

Cutaneous blood flow at the site of the forearm was continuously measured before, during and after occlusion of the upper arm. To obtain occlusion a cuff was placed around the upper arm of the baby and insufflated to a pressure of 100 mm Hg. In each baby, ten consecutive occlusions of the upper arm lasting 1 min each, with 5 min intervals were done. Simultaneously, recordings were made of heart rate, respiratory rate (Hewlett Packard 78214-A), skin temperature on the chest and the forearm and of the rectal temperature (Yellow Springs thermistor probe 409 B). Transcutaneous PO2 and pCO2 (Radiometer TCM2) were measured on the chest. All signals were recorded on an 8 channel strip chart recorder (Beckmann). Veneous hematocrit of each baby was measured on the same day by the coulter counter method (Coulter electronics).

Cutaneous blood flow was measured according to the laser Doppler method, described by others (14, 15). In the present study a recently developed diode laser Doppler flowmeter (Diodopp) was applied, which has the light source and detectors integrated in the sensor (16). Optical fibres, sensitive to movement artefacts, are therefore not used. The frequency shift of laser light, caused by the moving red blood cells, is used to determine blood flow in a small measuring volume of approximately 2–4 mm3 of the skin. The advantage of this method is that blood flow can be measured continuously and noninvasively over a long period without hardly any disturbance of the infant. The sensor was placed on the volar side of the forearm in each infant. After exclusion of the recordings disturbed by arm movements, a total of 157 measurements were analysed.

Data analysis. Laser Doppler flow is expressed in mVolts (mV). The preocclusional blood flow or baseline flow was defined as the mean cutaneous blood flow over 1 min prior to occlusion (Fig. 1). After occlusion the reactive hyperaemia response of the cutaneous blood flow was recorded. We measured the maximal blood flow after occlusion (Vmax), and the time in seconds to reach the maximal response (tmax). Furthermore the time in seconds for blood flow to return to baseline after maximal flow (tend) and the percentage increase in cutaneous blood flow above preocclusional level (overshoot) (17) were recorded. The mean values of the consecutive measurements in each infant were calculated. For statistical analysis the Pearson cross correlation test and multiple regression was used. A p value of less than 0.05 was considered to be significant.

RESULTS
A representative recording of cutaneous blood flow before, during and after 1 min occlusion of the upper arm is shown in Fig. 1. We were able to detect a reactive hyperaemia response in every infant studied (Fig. 2). There was a large variability in the magnitude of the baseline flow and the reactive hyperaemia parameters as shown in Table 1. The baseline flow was 1 954 ± 934 mV, the Vmax was 2 640 ± 1 050 mV and the overshoot was 74.6 ± 34%. The tmax and tend were 35.6 ± 14.6 sec and 7.6 ± 4.0 sec, respectively. All values are mean values ± SD. The tmax was inversely
correlated with the hematocrit, \( r = -0.62, p<0.05 \) (Fig. 3). There was no significant correlation between baseline flow or any of the other reactive hyperaemia parameters and the following variables: postconceptional and postnatal age, birthweight and skin, rectal and incubator temperature. During each occlusion we found a considerable decrease in transcutaneous oxygen tension, the mean decrease being 56.9\% ± 13.4\% (mean ± SD) of the preocclusive level. The transcutaneous carbon dioxide tension increased slightly during occlusion with a maximum increase of 1 mmHg. There was virtually no change in skin temperature during the recordings.

**DISCUSSION**

The results of our study show that a reactive hyperaemia response is elicitable in infants with a postconceptional age ranging from 28 weeks onwards. This indicates that this autoregulatory mechanism of blood supply in the skin exists in premature newborns. No influence of postconceptional age could be demonstrated. We found a variable baseline flow and variable reactive hyperaemia responses in individual
infants. The interindividual variability of the cutaneous blood flow and the reactive hyperaemia response were even more impressive. Large, sometimes more than tenfold, differences were seen. Laser Doppler skin blood flow recordings in adults show the same amount of variations in skin blood flow (18, 19) and in reactive hyperaemia parameters (19).

It is known that under resting conditions cutaneous blood flow varies continuously (8, 20). These variations are due to several mechanisms of central and local origin. The central nervous regulation mechanism is most important in the control of the vascular tone and, consequently, the cutaneous blood flow. Changing sympathetic activity causes vasomotor changes, which are a reflection of variations in the smooth muscle tension (21) and therefore in a variable cutaneous blood flow.

The locally originated regulation mechanisms such as hypoxia and hypercapnia are probably more important during the reactive hyperaemia following occlusion. The large variability in reactive hyperaemia can therefore be explained by changes in local factors, superimposed on a centrally regulated, variable cutaneous blood flow. The large interindividual variability in our study cannot be explained by different behavioral states, because 146 of the 157 analysed occlusions were recorded in infants during active sleep.

The reactive hyperaemia and baseline flow seem not to be influenced by postconceptional age, postnatal age or birthweight in our study. The literature on this subject is rather controversial. Berg & Celander (4) found a higher maximal hyper-

aemia response and a higher baseline flow in premature infants compared to term infants. Wu (5) found a decrease in cutaneous blood flow at rest with increasing postconceptional age. Riley (7) found a significantly greater blood flow in mature infants compared to premature infants, but found no effect of increasing maturity on blood flow in premature infants. The difference between all those studies and our study however is that we measured cutaneous blood flow alone, whereas Berg, Wu and Riley measured cutaneous and muscular blood flow together using venous occlusion plethysmography. Therefore it is difficult to compare our results with data obtained by venous occlusion plethysmography.

Rather surprising was the finding of a decreased $t_{\text{max}}$ in infants with an increased systemic hematocrit (Fig. 3). Although the hematocrit in the microcirculation is only a fraction of the systemic hematocrit (22) and does not change in the same proportion as the systemic hematocrit (23), the changes in the microcirculatory hematocrit are likely to be in the same direction. In theory, the inverse correlation between systemic hematocrit and $t_{\text{max}}$ ($r = -0.62$, $p=0.001$) can be understood from the dynamic behaviour of flow in blood vessels. After releasing the cuff the onset of flow starts with an acceleration and the maximal flow will be reached sooner when the viscosity is increased, since the maximal flow is lower when viscosity, i.e. hematocrit is increased. The maximal flow, however, was not related to the hematocrit in the present study and therefore this explanation is unlikely.

It can also be assumed, that the hematocrit changes with increasing postconceptional age. Multiple regression, however, revealed a negligible influence of the postconceptional age on $t_{\text{max}}$.

Mirhashemi et al. (23) suggested a specific effect in the skin circulation during hemodilution, in which arteriolar vasoconstriction is a compensatory mechanism, shifting the blood flow to other organs with higher oxygen demands. A reversed reaction, vasodilatation of cutaneous arterioles in case of higher hematocrits, might be possible. As the flow in the arterioles is only a small fraction of the flow measured by laser Doppler flowmetry and the arteriolar vasodilatation is most likely to influence only the first part of the reactive hyperaemia response, this might also be an explanation for the decreased $t_{\text{max}}$ at higher hematocrits.

There is a difference in reactive hyperaemia after short term occlusion—usually defined as an occlusion shorter that 2 or 3 min—and after long term occlusion. It is known, that in long term occlusions, metabolic factors such as acidosis, hypercapnia and tissue lactic acid levels play an important role (24). The mechanism of reactive hyperaemia after a short term occlusion is not exactly known. One suggestion is that the vasodilatation after a short term occlusion is directed by hypoxia. Fairchild et al. (25) experimentally continued the hypoxia in dogs after release of the occlusion and found that the state of vasodilatation remained. We conclude that postocclusive reactive hyperaemia of the cutaneous circulation is well developed in premature newborns. An inverse correlation was found between hematocrit and time to reach maximal flow after occlusion. We found no change in the reactive hyperaemia response with increasing age. The large interindividual differences between reactive hyperaemia parameters and baseline flow indicate, however, that the transversal study design is less suitable in studying cutaneous blood flow. A longitudinal study seems more appropriate.
