Poly(ethyleneimine) modified filters for the removal of leukocytes from blood

Anton Bruil, Hieke A. Oosterom, Ingeborg Steneker, Bert J. M. Al, Tom Beugeling, Willem G. van Aken, and Jan Feijen

1 Department of Chemical Technology, Biomaterials Section, University of Twente, P.O. Box 217, 7500 AE Enschede, The Netherlands; and 2 Central Laboratory of the Netherlands Red Cross Blood Transfusion Service, P.O. Box 9190, 1006 AD Amsterdam, The Netherlands

Polyurethane membrane filters and filters coated with poly(ethyleneimine) were used to investigate the influence of leukocyte adhesion during filtration. Treatment of the filters with an aqueous solution of 1% (w/v) poly(ethyleneimine) (PEI) led to the introduction of amine groups at the filter surfaces, as was confirmed by X-ray photoelectron spectroscopy. The modification procedure did not significantly change the porous structure in the filters, as was demonstrated by SEM and porometry. Using 14C-labeled poly(ethyleneimine) it was shown that nearly a complete coverage (~0.1 mg/m²) was achieved that did not desorb from the filter surface during contact with blood plasma. When the filtration was carried out with purified leukocytes in the absence of red cells, platelets, and blood plasma, the number of cells removed by modified filters (>95%) was significantly higher as compared to the removal with unmodified filters (~80%). However, no significant differences between the filters were found when the filtration was performed with whole blood. This finding was unexpected, because it was shown before that immobilization of poly(ethyleneimine) on solid polyurethane film surfaces promoted the adhesion of leukocytes from whole blood. Apparently, the adhesive properties of the PEI diminish during filtration. Filter coating of commercial leukocyte filters composed of polyester fibers also had no effect on the removal of leukocytes from whole blood. It was postulated that morphological factors, such as filter shape, roughness, tortuosity, and porosity rather than the physicochemical properties of the filter surface influence cell adhesion to the filter surface, and through that the filtration process.

INTRODUCTION

Leukocyte depleted blood products, particularly red-cell concentrates, are clinically used to avoid negative side effects in recipients after transfusion. Such leukocyte-associated post-transfusion complications include human leukocyte antigen (HLA) alloimmunization, graft-versus-host disease, platelet refractoriness, and transmission of viruses. Amongst the various techniques to remove leukocytes from blood, filtration has become a popular method because of its convenience and low costs. Leukocyte filters have been specially developed for this purpose and they generally consist of fibrous materials made of nylon, polyacrylonitrile, cotton wool, cellulose acetate, or polyester. Currently available filters remove more than 99% of the leukocytes from whole blood, while red cell loss is small.

*To whom correspondence should be addressed.

Much has been speculated about the mechanism of leukocyte depletion by these filters. Several authors have propounded that the removal of leukocytes is accomplished by selective adhesion of leukocytes to the filter material. In a previous study on the mechanisms of leukocyte filtration, in which polyurethane (PU) membranes were used as model filters, it was demonstrated that adhesion rather than mechanical sieving governs the filtration process. Similar results have been reported by Steneker and Biewenga who studied a commercially available filter type. However, the quantitative effect of leukocyte adhesion on the efficacy of leukocyte filters was not conclusively tested since the observations were based on studies in which only one particular type of filter was used. In order to demonstrate the relationship between leukocyte adhesion and leukocyte removal, structurally equivalent filters that have different surface properties with respect to leukocyte adhesion should be compared. Such model filters may be prepared by surface
modification of leukocyte filter materials with a well defined porous structure.12

In order to optimize leukocyte adhesion to PU membrane filters, we have previously studied the effect of ionizable functional groups13 and wettability14 on the in vitro adhesion of leukocytes to modified PU films under static conditions. Of all surfaces tested, the number of adherent leukocytes as a function of time was highest for the PU surfaces modified with poly(ethyleneimine) (PEI). This was explained by short range interactions between amine groups of the immobilized PEI and specific groups at the cell surface of leukocytes. When the efficacy of PEI modified solid films was studied under flow conditions, the rate, and the presence or absence of Ca2+ and Mg2+, plasma, and platelets in the cell suspension medium.15 The hypothesis that the filter efficacy is related to the extent of leukocyte adhesion, we have performed filtration experiments with purified granulocyte suspensions in phosphate buffered medium. In this way a direct comparison with the previous results of in vitro leukocyte adhesion studies13 is possible. In addition, standard blood filtration experiments were performed with both PU membrane filter and commercial filters, either PEI modified or unmodified.

MATERIALS AND METHODS

Membrane preparation

Series of polyurethane (PU) membrane filters were prepared from medical grade Pellethane 2363-80AE (Dow Chemical Nederland BV, Delfzijl, The Netherlands), using standard salt suspension techniques.12 To remove low molecular weight fractions, the polymer was first purified by slowly adding a 5% (w/v) solution of PU in dimethylformamide (DMF) to a 10-fold excess of water whilst stirring at high speed. The precipitate was collected by filtration, and dried in vacuo at 60°C.

Membranes with relatively small pores (type 15.1; Table I) were prepared from a solution of 9% (w/v) PU in DMF in which 75% (v/v, with respect to PU) of powdered magnesium carbonate, (Janssen, Beersel, Belgium), particle size <1 µm, was suspended. The suspension was treated ultrasonically for at least 1 day to break down particle aggregates. After degassing, thin films (500 µm) were cast from these suspensions on clean glass plates, after which the PU was coagulated by immersing the plates in ethanol for 20 min. Thereafter, the salt particles were dissolved by extraction with 3 M hydrochloric acid.

Membranes with larger pores (types 15.2, 15.3, and 15.4; Table I) were prepared from solutions of PU in

†Representing nonwoven layers from coarse and fine filter sections of the commercial PET filters used.
DMF (7%, w/v) in which particles of sodium citrate (Janssen, Beerse, Belgium) with size distributions of 0–38 μm, 38–63 μm, and 63–106 μm, respectively, were suspended. Particle fractions with these distributions were obtained by sieving. For the respective membranes, the concentration of particles used was 88, 89, and 90% (v/v, with respect to PU). Films of these suspensions were prepared and coagulated as described above. The salt particles were removed by washing with water.

Membrane type 13 was prepared as described for membrane type 15.2, and membrane type 14 and 16 were prepared as described for membrane type 15.3. In Table I further information about the membrane characteristics are given.

After preparation, all membranes were washed with distilled water, rinsed in ethanol, and finally dried in air. Membranes were kept dry in the dark at room temperature.

Filter preparation

Model filters were prepared by stacking membranes described in the membrane preparation section. First, thin filter layers with a diameter of 50 mm were cut from a stack of 4–5 membranes. Several of these layers, with a total thickness of ~3 mm, were then mounted together in a special polycarbonate filter housing (Schleicher & Schuell, type FP 050/0). To achieve sufficient filter capacity, two of these filter units were connected (Fig. 1). Both symmetric and asymmetric filters were prepared. Symmetric filters were composed of identical membranes in order to obtain a uniform pore size distribution, typically ~25 μm, throughout the filter. Asymmetric filters were composed of a stack of different membranes, in such a way that the average pore size decreased in the direction of blood flow through the filter. These filters were arbitrarily composed as follows; 4 times type 15.4, 12 times type 15.3, 4 times type 15.2, and 5 times type 15.4, respectively.

Commercially available Optima Cellselect leukocyte filters (NPBI, Emmer-Compascuum, The Netherlands) were used to investigate PEI filter modification during routine blood filtration. These filters consist of poly(ethylene terephthalate) (PET) fibers and can be subdivided in three different compartments, i.e., a prefiltter, a course main filter, and a fine main filter, varying in thickness, fiber size, and porous structure.

Commercially available Optima Cellselect leukocyte filters (NPBI, Emmer-Compascuum, The Netherlands) were used to investigate PEI filter modification during routine blood filtration. These filters consist of poly(ethylene terephthalate) (PET) fibers and can be subdivided in three different compartments, i.e., a prefiltter, a course main filter, and a fine main filter, varying in thickness, fiber size, and porous structure.

Filter modification

Before modification, filters described in the filter preparation section were first thoroughly rinsed with distilled water for 30 min (2.5 mL/sec). Coating with poly(ethyleneimine) (PEI 600; mol. weight 40,000–60,000; Sigma, St. Louis, MO) was achieved by slowly perfusing the filters with a solution of 1% (w/v) PEI in distilled water (pH 11) for 1 h (0.5 mL/sec). Weakly adsorbed PEI was removed by rinsing with distilled water followed by rinsing with phosphate buffered sodium chloride solution (PBS) for 5 min each (2.5 mL/sec). The coated filters were then thoroughly washed with distilled water for 1 h (2.5 mL/sec). To dry the filters, they were removed from the filter housing and exposed to air. Commercial filters were flushed overnight with clean dry air until their weight remained constant.

Control filters, which will be referred to as unmodified, were treated as described above, except that the PEI solution was replaced by distilled water. All filters were stored dry in the dark at room temperature until use.

Characterization of the filter structure

Surfaces and cross-sections of the membranes were examined by scanning electron microscopy (SEM; Jeol, type JSM-35 CF). Pore size distributions were de-
that pore size distributions are Gaussian, so that average pore size and a standard deviation can be defined.

The average pore size throughout a membrane was determined by porometry. Membranes or layers from the commercial filter were soaked with a special inert solvent (Porofi; Coulter Electronics GMBH, Krefeld, Germany) to fill all pores. A Coulter porometer (Coulter Electronics, type I) was used to measure the pressure increase that is needed to remove the fluid from the sample. With the porometer the average pore size can be automatically calculated from the pressure curve. All measurements were carried out in triplo.

The porosity, or pore volume fraction, of the membranes was determined in duplo from the weight and volume of dry samples. Sample volumes were calculated from the membrane thickness, as averaged from five measurements (SEM). For calculating the porosity, the density of air was neglected compared to the density of PU (1.13 kg/m³, according to the manufacturer).

Characterization of the filter surface

X-ray photoelectron spectroscopy (XPS) was used to analyze the elemental composition of the filter surfaces. Samples were arbitrarily cut from representative layers, obtained by section of the filter into separate membranes or nonwoven layers. XPS measurements were performed with a Kratos XSAM 800 (Kratos analytical, Manchester, UK), using X-rays from a Mg-Kα source (15 kV/20 mA) at a take-off angle of 90° between the filter surface and the analyzer. Under these conditions, the detection depth was about 7 nm. For quantitative analysis, detail scans were made of the C1s, O1s, and N1s peaks (diameter of the spot size 3 mm). Empirically derived sensitivity factors were used to convert peak areas in surface elemental composition.

Solid PU and PET films were used as reference samples. Solid PET films (Lux Thermanox 5410, Miles Scientific Laboratories, Naperville, USA) were cleaned by two-fold sonication in dichloromethane and acetone respectively. Solid PU films were cast from a 10% (w/v) solution of the PU in tetrahydrofuran, and cleaned by two-fold sonication in cyclohexane and ethanol, respectively, essentially as previously described. Clean solid films (2 × 2 cm) were coated with PEI by immersing the films for 1 h in a solution of 1% (w/v) PEI in distilled water. Weakly adsorbed PEI was removed by three-fold sonication in PBS and distilled water respectively.

PEI desorption

The stability of the PEI coating on PU membrane filters was studied using 14C-labeled PEI (14C-PEI), which was prepared by reductive methylation of PEI with 14C-formaldehyde (NEN Research Products, ‘s Hertogenbosch, The Netherlands) according to a procedure described by Okahata and Kunitake. The reaction was performed by adding 0.5 mmol 14C-formaldehyde (0.25 mCi) and 8 mmol formic acid to a solution of 50 mL of 4% (w/v) PEI in water. The mixture was refluxed for 48 h. After completion of the reaction, 14C-PEI was separated from unreacted formaldehyde by dialysis against water. The product was concentrated by freeze-drying. The labeling reaction resulted in the incorporation of 6–7 methyl groups per molecule PEI, i.e., approximately 0.5% of the total number of amine groups in PEI was methylated. The 14C-PEI had a specific activity of 0.1 mCi/g PEI.

Polyurethane membrane filters were modified with 14C-PEI and dried according to the procedure described in the filter modification section. Desorption of 14C-PEI from the modified filters was tested by slowly perfusing (0.5 mL/sec) the filters with successive 500 mL aliquots of solutions used in filtration experiments. For this purpose, PBS, 0.5% (w/v) human albumin in PBS, and 10% (v/v) human plasma in PBS were used in succession. To determine the amount of 14C-PEI desorbed from the filter, samples of 2 mL were taken from the eluent and added to 18 mL AquaLuma (Hicol, Oud-Beijerland, The Netherlands). The radioactivity of these samples was measured using a liquid scintillation counter (LKB-Wallac, Rackbeta 1219). To determine the amount of 14C-PEI remaining in the filter after the different rinsing procedures, the filter materials were removed from the filter holder, and separated into six layers. Each layer was cut in small pieces, and added to 18 mL of AquaLuma. The radioactivity of these samples was measured by liquid scintillation counting. After correction for background radiation, the amount of 14C-PEI bound to the filter was calculated, and expressed as a function of the eluted volume.

The extent of 14C-PEI surface coverage was also determined for solid PU surfaces. Solid PU films were prepared and modified as described in the surface characterization section. The radioactivity of the solid 14C-PEI modified films was measured as described for the membrane filters in the previous section.

Granulocytes

Granulocytes were isolated from freshly collected citrated human blood, as described previously. One unit (500 mL) of blood was centrifuged at 400 g for
BLOOD LEUKOCYTE FILTERS 1257

The cell cells were fractionated by centrifugation for 20 min at 1000 g (room temperature). The cells from the pellet formed below the Percoll layer were collected. In order to lyse erythrocytes, cells were resuspended in ice-cold ammonium chloride medium (155 mM NH₄Cl, 10 mM KHCO₃, and 0.1 mM EDTA; 295 mM, pH 7.4). To complete the lysis, the suspension was gently shaken for 20 min while kept on ice. To remove red cell stroma and hemoglobin, the suspension was centrifuged at 4°C for 5 min at 400 g and the granulocyte containing pellet was resuspended in medium-G. This procedure was repeated 3 times.

The remaining granulocyte suspension was adjusted to 1.0 × 10⁶ cells/mL in medium-G, and characterized using a flow cytometer (Technicon, type H1). The purity of the granulocytes was always higher than 95%. Monocytes were the main contaminants. The viability of the cell suspensions was always more than 97%, as was determined by trypan blue exclusion. It was shown with monoclonal antibodies against B13.9 antigen, which is upregulated from secondary and tertiary granules in the granulocyte membrane upon activation, that the cells were not activated during the isolation step. Before being used in filtration experiments, leukocyte suspensions were stored at room temperature for not more than 1 h.

Packed red blood cells (RBC)

Blood from healthy human donors was collected in blood bags containing citrate-phosphate-dextrose-adonine (CPDA). After storage for 10–15 h at 20°C, the bags were centrifuged for 10 min (3600 g at 20°C) to separate the plasma from the packed blood cells (RBC). After removal of supernatant plasma approximately 300 mL of RBC was diluted with 150 mL of an aqueous solution containing 0.9% sodium chloride (saline) to a hematocrit of ~60%. The cell suspension thus prepared contained most of the red cells, platelets, and leukocytes present in the original unit of blood. Filtration experiments were performed within 16 h after blood collection.

Filtration procedure

Filtration experiments with membrane filters were carried out using the system schematically depicted in Figure 1. The difference in height between the reservoirs and the filter was approximately 60 cm. The hydrostatic pressure was kept constant during filtration. Before filtration, filters were first rinsed with 500 mL of saline to repel air and to wet the filter surface. The flow was then adjusted with saline in the range of 0.04–1 mL/sec, by means of a valve connected to the filter outlet. Filtration was started by connecting the blood cell reservoir to the filter. In case of RBC filtration the initial flow decreased rapidly due to the high viscosity of the cell suspension as compared to saline, but remained constant after filtration of approximately 20 mL. The initial flow did not change when purified granulocyte suspensions were used. During filtration samples of the filtrate, typically 10 mL aliquots, were collected and analyzed. All experiments with modified and unmodified membrane filters were carried out in pairs, i.e., one cell suspension was used for both experiments. Replicate experiments were performed 6 times.

Filtration experiments with commercial leukocyte filters were carried out according to blood bank standard procedures. Before filtration, the filters were rinsed with 200 mL of saline. RBC was then filtered at a standard blood flow of approximately 0.4 mL/sec. After filtration of one unit of RBC, the filter was rinsed with 100 mL of saline to recover red blood cells from the filter bed. The complete filtrate was collected and analyzed. Replicate experiments were performed 6 times.

Analysis of the filtrate

Purified granulocyte suspensions were analyzed using a micro cell counter (Sysmex, model F-800), following standard procedures. Total leukocyte counts in blood samples were determined with a Coulter counter (Coulter Electronics, type ZF/C1000). Aliquots of 20 μL were diluted with 10 mL electrolyte containing solution. Lysis was induced with 2 drops of a saponin containing electrolyte solution. Remaining particles were then counted in 0.5 mL lysate sample. Measurements were carried out in in duplo.

Since the detection limit of the Coulter counter does not allow the detection of leukocyte counts less than 100/μL, a flow cytometric technique was used to detect leukocytes in samples obtained after filtration experiments with commercial filters. This technique was also used to count cells of different leukocyte subpopulations. In experiments with symmetric membrane filters, however, relative concentrations of monocytes, lymphocytes, and granulocytes in blood samples were determined microscopically, after staining with May-Grünwald/Giemsa dye.

Analysis of the filter materials after filtration

After filtration, some membrane filters were used for further evaluation. When experiments were
performed with purified granulocyte suspensions, filter samples were prepared for scanning electron microscopy (SEM). After filtration, the filters were fixed by slow perfusion with a solution of 2% (v/v) glutaraldehyde in PBS for 10 min. The filter materials were then detached from the filter housings, and dried in air. Small samples, cut from the membranes, were dehydrated by immersion for 10 min in successively 25, 50, and 75% ethanol in water, and twice in 98% ethanol. After drying in a vacuum desiccator the samples were sputter-coated with gold and examined by means of a scanning electron microscopy (JEOL, type JSM 35 CF) using a 15 kV accelerating voltage.

Samples were prepared for light microscopy by taking small parts (about 1 cm²) from the filters, which were then fixed with formaldehyde containing solution as described elsewhere. Fixed samples were embedded in methacrylate resin, according to standard procedures. Sections of 7 µm were cut with a microtome. After staining with hematoxilin solution (Delafield; Merck, Darmstadt, Germany), the samples were studied with a light microscope (Leitz, Ortholux II POL-BK).

**RESULTS AND DISCUSSION**

Filter preparation and modification

Filter preparation and characterization

SEM micrographs of the membranes used in this study (Fig. 2) show open and cellular pore structures, with relatively narrow pore size distributions as compared to nonwoven structures of commercial filters (Fig. 3). Pore sizes determined with the Coulter porometer, which represent the average pore size throughout the membranes \(d_{av}\), were in reasonable agreement with the pore sizes measured at both sides of the membrane surface using SEM \(d_{bottom}, d_{top}\) (Table I). This finding demonstrates the symmetric nature of the membranes. Consequently, in further experiments no distinction was made between top and bottom side of the membranes.

The surface elemental composition of the membranes was routinely determined using XPS (Table II). When the results of XPS measurements were compared for different samples, it should be remembered

---

**Figure 2.** SEM micrographs of the top side of membranes used in this study. From left to right, the micrographs show membrane type 15.4, type 15.3, type 15.2, and 15.1. Original magnification 200×.
that empirically derived sensitivity factors were used to calculate the relative elemental composition of the sample surface. These sensitivity factors were derived for smooth solid surfaces, whereas the membrane surfaces were porous. Surface porosity may substantially affect the average take-off angle of emitted electrons, thereby influencing the detection depth. Strictly, a correction for the sample porosity should be made to allow a direct comparison of samples with different morphologies. Since we were not able to make such corrections, the XPS data for different kinds of samples should be compared with some reservations. Nevertheless, the surface elemental composition of porous PU membranes (~80% C, ~18% O, ~2% N) agreed well with the surface composition of solid PU films.

Commercial filters, composed of PET fibers, were also characterized by XPS (Table II). The surface composition found for solid control films of PET agreed well with theoretical composition of PET (71.4% C, 28.6% O). A large deviation of this theoretical composition was, however, found for the surface of PET fibers in filters. Probably the PET fibers in these filters, as obtained from the manufacturer, were not completely pure. It has been reported that the surface

**PEI modification**

Treatment of the filters with a solution of 1% (w/v) PEI in water led to the adsorption of PEI to the filter material. To remove excessive and weakly bound PEI from the filters, rinsing with PBS and water was performed. The efficiency of this procedure was tested for a PU membrane filter with the use of 14C-labeled PEI (14C-PEI). It appeared that the amount of 14C-PEI in the filter rapidly decreased during the initial stage of the rinsing procedure, but leveled off after rinsing the filter with 15 L of water, i.e., >1000 times the void volume of the filter (Fig. 4a). When the modified membrane filters were mounted in clean housings, no significant desorption of 14C-PEI occurred during successive perfusion with PBS, 0.5% (w/v) human albumin in PBS, and 10% (v/v) plasma in PBS after a model filtration experiment (curve B). Error bars are standard deviations (n = 3).

The surface concentration of PEI adsorbed onto the PU membrane filters can be estimated. Assuming an average pore size of 30 µm for the membrane filter used (Table I, type 14) and a total filter volume of 12 mL (diameter 50 mm, thickness 6 mm), and using an equation for the relation between specific surface (S) and average pore diameter ($d_{av}$) of foams, $S = 4/d_{av}$, as derived by Aubert, the accessible surface for PEI adsorption in the complete filter is approximately 1.6 m². Then, a coverage of $\sim0.1$ mg PEI/m² of membrane surface can be calculated. This result agrees well with the amount of 14C-PEI that had been adsorbed under comparable conditions to the surface of a solid PU film in a control experiment ($\sim0.12$ mg/m², Fig. 5). In the literature, surface coverage varying from 0.1–0.5 mg PEI/m², mainly depending on the molecular weight of the PEI, is generally interpreted in terms of a monolayer adsorption. It is therefore likely that nearly a complete coverage of the filter surfaces with PEI has been achieved here. It cannot be excluded, however, that small uncovered areas may also occur.

**Filter characterization after modification**

The results of XPS (Table II) demonstrate a significant increase of the concentration of nitrogen at the surface of PEI modified membrane filters as compared to unmodified membrane filters, apparently caused by incorporation of amine groups. Remarkably, the surface nitrogen concentration for porous PEI modified membranes was generally found to be higher than for PEI modified solid films. It is likely that the removal of weakly bound PEI from the surface was more effective for solid films than for porous membranes. To remove weakly bound PEI from solid films, PEI treated films were sonicated in PBS and distilled water for several times. It turned out in practice, however, that this procedure damaged the porous structure of the membranes. Therefore, a rinsing procedure was used to remove weakly bound PEI from the membranes. The fact that relatively high concentrations of nitrogen were found on membranes with relatively small pores (e.g., membrane type 15.1, Table II) suggests that the efficiency of the rinsing procedure increased with the pore size of the membrane. This
Filtration experiments

Filtration of granulocyte suspensions using membrane filters

We have previously studied the adhesion of granulocytes from various media to unmodified and PEI modified surfaces of solid PU films under controlled flow conditions. Although the absolute number of adherent granulocytes was largely influenced by the composition of the medium, the extent of adhesion was always larger with PEI modified surfaces as compared to unmodified surfaces. To test whether the PEI coating could be used to improve the depletion of granulocytes with leukocyte filters, suspensions of purified granulocytes in medium-G were filtered through unmodified and PEI modified membrane filters. The conditions in these experiments were better controlled as compared to whole blood filtration experiments, because the cellular composition of the suspension was exactly known and the influence of red cells, platelets, and plasma on the filtration process was excluded. In order to minimize the effects of mechanical trapping of cells in the filter pores, symmetric membrane filters in which the average pore size was large (type 16; \( d_{av} \sim 25 \, \mu m \)) as compared to the diameter of granulocytes (5–8 \( \mu m \)) were used.

The depletion of granulocytes by unmodified and PEI modified membrane filters was measured as a function of the filtered volume. More than 95% of the granulocytes were initially removed by the PEI modified filter, whereas the depletion of cells by the unmodified filter (\(<80\%\)) was significantly lower (Fig. 6). This finding can be explained by differences between the numbers of adherent cells to the filter membranes, because the porous structure of both filters was the same. When filtration experiments were performed at a higher flow rate of 0.20 mL/sec, instead of 0.04 mL/sec, the depletion of granulocytes by both membrane filters was substantially lower (Fig. 7). This effect of flow on the removal of cells by the membrane filters confirmed the importance of cell adhesion phenomena in these experiments. When the flow rate is increased, the residence time of cells in the membrane filter is decreased and as a consequence the chance of a cell to effectively collide with the surface of the filter is reduced. A similar effect of flow on leukocyte retention in columns of siliconized glass beads was reported by others.

SEM examination of the membrane filters after filtration confirmed that the granulocytes were depleted by adhesion to the membrane filter surface in both filter types. Mechanical trapping of the cells by small pores or dead spaces in the membrane filters was not observed. No significant differences in cell morphology were observed between granulocytes adherent to the surfaces of unmodified (Fig. 8[A]) and PEI modified membranes (Fig. 8[B]).
Figure 6. Recovery of granulocytes in the filtrate after filtration of granulocytes in medium-G through unmodified (open circles) and PEI modified (closed circles) membrane filters (type 16), flow rate 0.04 mL/sec. Graphs show the percentage of granulocytes in the filtrate \(100 \times C_{out}/C_{in}\) as a function of filtered volume ± SD \((n = 4)\).

It is of interest to compare the extent of cell adhesion to the membrane filters with the extent of cell adhesion to unmodified and PEI modified solid films, which were previously used under static and flow conditions. For the present experiments it was calculated that the ratio between the number of adherent cells in the PEI modified filters and in the unmodified filters was approximately 1.2 for both flow rates, whereas the effect of the PEI coating on the extent of cell adhesion was significantly higher in our previous experiments. Apparently, the efficiency of the PEI coating to improve cell adhesion to the membrane filter is relatively low. This is probably due to a poor interaction between the granulocytes and the filter membranes. The absence of red cells in the cell suspension used in the present experiments diminishes the driving force of granulocytes to migrate and adhere to the filter membranes. When granulocytes reach the filter surface under these circumstances, the contact time between the cell and the surface will only be short as a result of the irregular structure in the membrane filters. We have previously reported that the difference between the adhesion of granulocytes to unmodified and PEI modified surfaces of solid films is relatively small at short exposure times, as compared to longer exposure times.

In conclusion, the results of filtration experiments with granulocytes prove that the PEI coating can lead to an increase of the extent of leukocyte adhesion during the filtration process, which may result in an improved filter efficacy. The effect of PEI to enhance leukocyte adhesion to membrane filters is, however, small as compared to leukocyte adhesion to solid film surfaces.

Filtration of whole blood using membrane filters

The effect of PEI coating on the efficiency of leukocyte filters under standard filtration conditions was studied, using both symmetric (type 13; \(d_{av} \approx 20 \text{\mu m}\)) and asymmetric membrane filters (type 15; \(d_{av} \approx 10-60 \text{\mu m}\)). The results of these experiments showed large variations, probably due to differences in the composition of blood collected from different donors. The total population of leukocytes in human whole blood generally varies between \(4 \times 10^6\) and \(11 \times 10^6\) cells/mL, and also the composition of this population, i.e., granulocytes \((2-6 \times 10^6 \text{ mL}^{-1})\), lymphocytes \((1.5-4 \times 10^6 \text{ mL}^{-1})\), and monocytes \((0.2-0.8 \times 10^6 \text{ mL}^{-1})\), may vary largely. These variations are likely to affect the filtration efficiency since different subpopulations of leukocytes are known to adhere to polymer surfaces to different extents. Also variations in the amount and type of other blood components may influence the efficiency of the filtration process. Red cells may play a role in the migration of leukocytes to solid surfaces under conditions of flow, and platelets may be involved in the adhesion of leukocytes to solid surfaces. Moreover, the presence of plasma proteins in the cell suspension medium is known to inhibit leukocyte adhesion. In order to avoid the effects of variations of different RBC suspensions, unmodified and PEI modified membrane filters were tested with the same RBC suspension in replicate experiments on 4 different days.

Figure 9 shows the recovery of leukocytes in the filtrate after filtration of RBC by unmodified and PEI modified symmetric filters as a function of the filtered volume. No significant differences were found between the unmodified and the PEI modified filter with respect to the recovery of leukocytes in the collected filtrate \((P = 0.4; \text{ two-tailed } t \text{ test for paired data sets}). To study the depletion of different leuko-
cyte subpopulations in detail, 70 mL of the filtrate was collected and analyzed to detect the amounts of granulocytes, lymphocytes, and monocytes. It was found that the removal of these subpopulations from RBC by the filters was largely dependent on the cell type (Fig. 10). In general, the symmetric membrane filters depleted more than 80% of the granulocytes, whereas the depletion of lymphocytes was less than 30%. This finding suggests that the efficiency of the filter depends on the extent of cell adhesion to the filter surface, since the recovery of different leukocyte populations was consistent with their adhesiveness to polymer surfaces reported in the literature. Relatively high concentrations of lymphocytes in filtered blood, as compared to other leukocyte types, have also been reported by other authors. However, the difference between the unmodified and PEI modified filters with regard to the recovery of granulocytes ($P = .13$), lymphocytes ($P = .29$), and monocytes ($P = .26$) in the filtrate was not significant (two-tailed $t$ tests for paired results). Apparently the PEI coating did not lead to a substantial increase of the number of leukocytes adhered to the membrane filter under the blood filtration conditions used in this study.

The results of a histological study of filter sections after filtration confirmed the contribution of adhesion of leukocytes in the filtration process. Figure 11 shows that leukocytes adhered to the surface of the membrane filters. No substantial differences were observed, however, between the unmodified (Fig. 11[A]) and the PEI modified membrane filters (Fig. 11[B]) with respect to the type, number, and morphology of adherent cells. In general, large numbers of cells, mainly granulocytes, were found to adhere to the upper parts of the filters, whereas almost no leukocytes were depleted in the bottom section of the filters. These findings are in agreement with our previous studies on the distribution of adherent cells in membrane filters.

Standard blood filtration experiments were also performed with asymmetric membrane filters. The average pore size of these filters gradually decreased from approximately 60–10 μm in the direction of blood flow. The asymmetric nature of the filter allows...
Figure 10. Recovery of different leukocyte subpopulations in the collected filtrate (70 mL) after filtration of RBC through symmetrical membrane filters (type 13), either unmodified (left bars) and PEI modified (right bars). Bars show the percentage of cells in the collected filtrate (100 \times C_{out}/C_{in}) \pm SD, as determined microscopically (n = 4).

A very close contact between cells and the filter surface in the bottom section, whereas early stage clogging of the filter is prevented by partial removal of cells in the top section. Adhesion of cells to the filter surface during the filtration was promoted by providing a relatively long residence time for the cells in the filter (flow \sim 0.04 mL/sec). Figure 12 shows the recovery of different types of leukocytes in the collected filtrate after filtration of 70 mL of RBC by unmodified and PEI modified asymmetric filters. The close contact between the leukocytes and the asymmetric filter surface resulted in a relatively high removal of leukocytes as compared to symmetric filters. However, again no statistical significance between the difference in leukocyte removal by unmodified and PEI modified filters was obtained.

Filtration of whole blood using commercial filters

Commercial leukocyte filters, composed of PET fibers, were used to evaluate the perspectives of the PEI coating in routine blood filtration. These filters were developed to remove at least 99% of the leukocytes in one unit (~400 mL) of RBC suspension. Filtration experiments were performed with unmodified and PEI modified filters, according to standard procedures used in blood banks to prepare leukocyte poor red cell concentrates. The results of these experiments show that more than 99.9% of the leukocytes in the RBC suspension were removed by the unmodified filters (Fig. 13). PEI coating of the filters did not significantly increase the extent of leukocyte removal by the filters (P \geq .26; two-tailed t test for paired results). Relatively less granulocytes as compared to lymphocytes were removed by the commercial filters, which is in contrast with the results obtained with the membrane filters used in this study. This difference is probably caused by the specific construction of the commercial filters, in which large amounts of lymphocytes can be efficiently removed by mechanical sieving in the bottom section of the filter. Lymphocytes are known to be less deformable as compared to granulocytes, and may thus easily be captured in small pores.

Evaluation of the filter behavior

The inability of PEI modified filters to improve the removal of leukocytes from blood was unexpected. We
Figure 12. Recovery of different leukocyte subpopulations in the collected filtrate (70 mL) after filtration of RBC through asymmetrical membrane filters (type 15), either unmodified (left bars) and PEI modified (right bars). Bars show the percentage of cells in the collected filtrate \((100 \times C_{\text{out}}/C_{\text{in}}) \pm SD\), as determined by flow cytometry \((n = 4)\).

Figure 13. Recovery of different leukocyte subpopulations in the collected filtrate (500 mL) after filtration of RBC through commercial leukocyte filters, either unmodified (left bars) and PEI modified (right bars). Bars show the percentage of cells in the collected filtrate \((100 \times C_{\text{out}}/C_{\text{in}}) \pm SD\), as determined by flow cytometry \((n = 6)\).

have previously studied the adhesion of leukocytes from medium-G to unmodified and PEI modified solid PU films under static conditions.\(^{13}\) It appeared that the number of adherent cells to PEI modified surfaces was approximately three times higher than on unmodified surfaces. Subsequently, we have investigated whether the enhancing effect of the PEI coating on leukocyte adhesion to solid films could be extended under conditions of flow.\(^{15}\) The results of this study again showed a difference between unmodified and PEI modified solid PU films with respect to leukocyte adhesion. Finally, we have tested the PEI modified solid films under conditions similar to those in standard blood filtrations, i.e., flow, in the presence of red cells, platelets, and citrated plasma diluted in saline.\(^{15}\) It turned out that the number of adherent leukocytes on PEI modified solid PU films was still five times higher than on unmodified solid films, although the extent of adhesion was substantially reduced in the presence of plasma.

In contrast to these previous experiments with solid films under flow conditions, no enhancing effect of the PEI coating on adhesion was found when leukocyte adhesion was studied with porous membranes under flow conditions. To explain this inconsistency, the effect of flow rate on leukocyte adhesion should be considered. For solid films, a maximum in cell adhesion was found when the shear rate was 30 sec\(^{-1}\).\(^{15}\) The shear rate (\(\tau\)) in the present membrane filters was estimated by assuming laminar flow (\(\nu\)) of the blood through nontortuous capillaries with a length of 6 mm and a uniform diameter (\(d\)) of 25 \(\mu m\), and using an equation, \(\tau = 8 \cdot \nu / d\), derived from the well known Poiseuille-Hagen equation.\(^{53}\) Thus, an approximate shear rate in the filters of \(\sim 30 \text{ sec}^{-1}\) was achieved by adjusting the flow rate to 0.20 mL/sec. Because of the large limitations of the flow rate calculations, and the complicated flow patterns in the filters as compared to the laminar flow in the experiments previously described,\(^{15}\) an experimental determination of the optimal flow rate in filters is preferred. It should be noted, however, that an optimal flow rate is not a prerequisite for enhanced leukocyte adhesion to PEI modified filters since the effect of PEI to promote cell adhesion to solid films was also observed at other flow rates.\(^{15}\) It is therefore not very likely that the inability of the PEI coating to improve the efficiency of leukocyte filters is due to a nonoptimized flow rate in these filters.

It is more likely that the difference between the results of the present filtration experiments and previously described adhesion experiments with the smooth surface of the solid films is due to the porous structure of the membrane filters. It is well known that cell adhesion depends on the curvature and texture of the substrate.\(^{47}\) For instance, it has been reported that the adhesion of platelets\(^{54}\) and erythrocytes\(^{55}\) to porous surfaces was diminished as a result of fluid flow through pores. On the other hand, fibroblasts adhere more firmly to porous surfaces as compared to solid surfaces.\(^{56}\)

Also surface roughness is known to affect cell adhesion. Chang et al. have reported that the extent of erythrocyte adhesion to a number of substrates was affected by surface irregularities.\(^{57}\) Rich and Harris found that macrophages preferentially adhere to rough surfaces as compared to smooth surfaces under flow conditions.\(^{58}\) Similar effects of surface roughness have been reported for the adhesion of platelets by Zingg et al.\(^{59}\) Guidoin et al. have recognized the effects of surface roughness in blood filters,\(^{50}\) and found that large numbers of adherent leukocytes and platelet aggregates were formed in macroaggregate filters with an irregular and imperfect surface texture,
as compared to filters with a smooth surface. The effect of surface roughness on cell adhesion has been attributed to the presence of gas nuclei and bubbles at rough surfaces, which may enhance cell adhesion.\textsuperscript{61}

Air nuclei at rough surfaces, which are preferentially formed at hydrophobic substrates, are known to activate the complement system,\textsuperscript{62} which mediates the adhesion of leukocytes to artificial surfaces.\textsuperscript{63,64} Less is known about the surface roughness in the present filters, but it is very likely that microscopic irregularities at the surface of the tested membranes (Fig. 2) may have influenced leukocyte adhesion during filtration.

It should be noted that the surface to blood volume ratio in filters is large as compared to solid films. Since the extent of complement activation is proportional to the surface area exposed to blood,\textsuperscript{65} the effect of complement activation on leukocyte adhesion may become significant in blood filters.\textsuperscript{66,67} The large surface to blood volume ratio in filters may also cause activation of platelets. Activated platelets secrete adhesive proteins such as fibrinogen, fibronectin, and von Willebrand factor,\textsuperscript{35,46} which may be adsorbed on the surface of both unmodified and PEI modified filters.

Effects of the filter structure may even counteract the effect of PEI. For example, since PEI modified PU surfaces are hydrophilic as compared to unmodified PU surfaces,\textsuperscript{13} the formation of air nuclei in filters, which may favor the adhesion of leukocytes to the filter surface, may be promoted in unmodified filters. The various effects of the filter structure on leukocyte adhesion may diminish the effect of the PEI coating on leukocyte adhesion in filters. In this context, the direct influence of the physicochemical properties of the filter material surface on leukocyte adhesion in filters may possibly be overestimated.

CONCLUSIONS

The main objective of this study was to investigate the role of leukocyte adhesion in the leukocyte filtration process. For this purpose we used a PEI surface modification procedure to prepare filters that were structurally identical, but had different surfaces properties with respect to leukocyte adhesion \textit{in vitro}. The present results confirm that adhesion of leukocytes on the filter material is important for removal of leukocytes, but an effect of the PEI coating on the extent of leukocyte adhesion was only significant when red cells, platelets, and plasma were absent in the filtration medium. This finding suggests that factors other than the physicochemical properties of the filter surface dominate leukocyte adhesion in the filters. In this respect, we recommend that the influence of filter surface texture on leukocyte adhesion, e.g., shape, roughness, tortuosity, and porosity, be further investigated.
