Keywords: Inventory, Service Logistics, Markov processes, Interval availability, Reliability, Supply chain management.

Abstract: In this paper we analyze the interval availability of a two-echelon, multi-item spare part inventory system. We consider a scenario inspired by a situation that we encountered at Thales Netherlands, a manufacturer of naval sensors and naval command and control systems. Modeling the complete system as a Markov chain we analyze the interval availability. We compute in closed and exact form the expectation and the variance of the availability during a finite time interval \([0, T]\). We use these characteristics together with the probability that interval availability is equal to one to approximate the survival function using a Beta distribution. Comparison of our approximation with simulation shows excellent accuracy, especially for points of the distribution function below the mean value. The latter points are practically most relevant.

1 INTRODUCTION

Nowadays, the aftersales service business represents a considerable part of the economy and, moreover, is continuously growing (AberdeenGroup 2005; Deloitte 2006).

Advanced capital goods such as MRI scanners, lithography systems, baggage handling systems, and radar systems, are highly downtime critical. The high criticality in these cases is due to lost production, missions that need to be aborted, patients that cannot be treated, and flights that are delayed or cancelled. So the customers of these advanced goods are not just interested in acquiring these systems at an affordable price, but far more in a good balance between the resulting Total Cost of Ownership (TCO) and system productivity throughout the life cycle, including the limitation of downtime. It is often the case that the system upkeep costs during the life cycle of the system constitute a large part of the TCO. However, for customers the system use rather than the system upkeep is their core business. Therefore, a major part of the system upkeep is preferably outsourced to the original manufacturer or to an intermediate service provider that can offer a good balance between the downtime and costs. For that reason, service contracts are made between the service provider and customers. These contracts specify the services provided by the supplier with their corresponding Service Level Agreements (SLAs), such as the time between system failure and time of fault resolution, and the system availability.

The SLAs are measured over a predetermined time window, e.g., a quarter or a year. For the service providers, it is essential that the service levels are attained, because in some cases penalties apply if an SLA target is violated. In case of a large scale service contract (the average performance over many systems is measured), the average performance should meet the target. If the number of systems covered by a contract is relatively small, we have inherent statistical variability and we need an additional buffer in performance to assure that the probability of not meeting the SLAs over the time window is still acceptable. We encountered such a situation at Thales Netherlands, a manufacturer of naval sensors and
naval command and control systems. There, a service contract typically covers a few systems only. In the literature, this issue is usually neglected. In this paper, we are mainly interested in the logistical delay due to the unavailability of spare parts, since this is the basis of current service contracts at Thales Netherlands. Moreover, the focus will be on SLAs that are based on the system availability during a predetermined period of time.

In service parts logistics there is usually a tradeoff between the cost involved in keeping the stocks very close to the customers sites or at a central depot, which can support multiple customers at the same time. Due to the risk pooling effect, it is more desirable for a service provider to position the stocks of spare parts centrally. However, having a strict SLA, e.g., 99% availability in a quarter, forces the service provider to move some spare parts closer to the customer sites. In addition, in order to reduce the system downtime and its critical consequences, the repair of a failed system is usually done by replacing the failed part with a new part. The failed part is sent to the repair shop, i.e., the inventory is managed using one-for-one replenishment, so an (s-1,s)-policy. This policy is justified by the fact that most parts are slow movers for which a replenishment order of size one is usually (near) optimal. (Sherbrooke 1968) was among the first to tackle the spare part optimization problem. He proposed the METRIC model that is based on the maximization of system availability subject to a constraint on the invested budget in spare parts. The main decision in METRIC is how much to keep in stock at each of the locations in the supply network. The METRIC model provides good approximations for multi-echelon spare part networks, especially in case of a high availability. (Graves 1985; Slay 1984) extended the METRIC model and proposed an improved approach called the VARI-METRIC. We note that the VARI-METRIC model is the approach used in most commercial software tools on spare parts optimization.

It is worth to mention that both METRIC and VARI-METRIC and most spare parts management theory are based on finding an optimal balance between the initial spare part investment and the steady state system availability, i.e., the fraction of time the system is operational during a very long (infinite) period of time. However, in practice we often see
that the agreed upon availability SLA is the average availability during a finite period, e.g., month, quarter, or year. Moreover, if the availability during a period of time is lower than a specific percentage, penalty rules apply. This motivates us to analyze the availability during a finite period of time, the so-called interval availability that is defined in reliability theory as follows, see, e.g., (Nakagawa and Goel 1973):

**Definition:** The system interval availability is defined as the fraction of time a system is operational during a period of time \([0,T]\).

Note that in (Barlow, Proschan, and Hunter 1965; Hosford 1960) the interval availability is defined as the *expected* fraction of time a system is operational during \([0,T]\). To avoid confusion in this paper and according to the previous definition the interval availability is a random variable that has a distribution. In addition, this probability distribution has a finite support between zero and one with probability masses at the points zero and one: There are strictly positive probabilities that (i) an operational system will not face any lack of spare parts during \([0, T]\), and (ii) a failed system waiting for a specific spare part will not be repaired by replacement during \([0, T]\). In practical instances, the first probability will be significant, and the second probability will be close to zero.

Our main contribution in this paper consists of the following points:

- We propose a computational efficient and accurate approximation for the interval availability of a multi-item system supported by a two echelon supply network. More specifically, our approximation is accurate in the practical case of systems with high average availability.
- As part of this approximation, we derive in closed-form the variance and the third moment of the cumulative sojourn time in a subset of states of Markov chain in a finite interval. In principle, we can also derive all the higher moments using the same approach.
- Using simulation we show that the survival function of the interval availability is not very sensitive to the order-and-ship time distribution at the points of survival function
that are below the expected availability. This justifies our Markovian approach, specifically, the assumption of exponential order-and-ship times.

The paper is organized as follows. In Section 2 we briefly review the related literature. Section 3 describes our model and the assumptions used to analyze the interval availability distribution of a two echelon, multi item supply network. In Section 4 we report our approximation where our key results are reported in a set of Theorems. In Section 5 we validate our approximation using simulation and evaluate the impact of the order-and-ship time on the interval availability. Finally, in Section 6, we conclude the paper and give some directions for further research.

2 RELATED LITERATURE

In this section we shall review the existing literature on interval availability. (Takács 1957) was among the first to analyze the interval availability distribution function of an on-off stochastic process. Takács result is in the form of an infinite sum of terms, each consisting of multiple convolutions. This result is hard to compute numerically. Approximation by fitting the on and off periods by a phase type distribution with two phases was proven to give accurate result with small computation time, see e.g., (van der Heijden 1988). Another approximation based on fitting the approximated first two moments, the hundred percent, and the nil probability of the interval availability in a Beta distribution was proposed in (Smith 1997). For an on-off two states Markov chain the first two moments of the interval availability are derived exactly in (Kirmani and Hood 2008). We note that in all these previously mentioned studies the underlying assumption is that the on periods are independent and the off periods are independent, moreover, all the on and off period are independent of each other, i.e., the on-off process can be represented by a renewal process.

(De Souza e Silva and Gail 1986) derived in closed-form the cumulative sojourn time distribution in a subset of states of a Markov chain during a finite period of time. The subset of states can, for example, represent the operational states of a system. Therefore, the
division of the cumulative sojourn time by the period length gives right away the system interval availability. We note that computing the full curve of the interval availability distribution using the method of (De Souza e Silva and Gail 1986) or its improved version in (Rubino and Sericola 1995) is time consuming. (Carrasco 2004) proposed an efficient algorithm to compute the interval availability distribution for the special case of the systems which can be modeled by an absorbing Markov chain. Note that in the latter three papers the renewal assumption of the on-off process is not necessary.

In this paper, we propose a numerically efficient approach to compute the distribution function of the interval availability. Our approach builds on the result of (De Souza e Silva and Gail 1986) extensively in order to compute in closed-form the first two moments of the interval availability. Note that these two moments were not derived previously in the literature for a Markov chain with more than two states. Moreover, we follow a similar approach to (Smith 1997) to approximate the interval availability by a Beta distribution using the first two moments in addition to the hundred percent probability of the interval availability.

Finally, we note that the analysis of a service level over a finite period of time is not only of interest in reliability theory but also in inventory management of fast moving products where demand is typically modeled by a Normal distribution. See, e.g., (Banerjee and Paul 2005; Chen, Lin, and Thomas 2003) in which the interest is on the expected fill rate over a finite period of time $T$ for a single site, single item system. In these papers it is proven that the expected fill rate over a finite period is larger than over the infinite period case. By using simulation (Thomas 2005) and experimental method (Katok, Thomas, and Davis 2008) evaluate the impact of $T$ and the demand distribution on the fill rate distribution over $T$. In the latter two papers, the simulation and the experimental tools are used due to the difficulty in explicitly computing the fill rate distribution during $T$. Tactical decisions on stock level to meet the time-based SLA in the case of multi-echelon, single item scenario was considered in (Cohen, Kleindorfer, and Lee 1986) and for the multi-item scenario in (Ettl, Feigin, Lin, and Yao 2000). The restriction in the analysis is that the time period should be equal to the
supply lead time of the part. More recently, the model in the latter two papers is extended and a scalability analysis is added in (Caggiano, Jackson, Muckstadt, and Rappold 2007).

3 MODEL

We consider a two-echelon, multi-item supply network. There is a single depot that supports multiple identical systems which are located at different bases. There is a single system per base. A system consists of multiple items that are subject to breakdown. These items are repairable and belong to the class of expensive slow-movers, i.e., they have low failure rates. The depot and the bases hold a safety stock of spares for each item. Upon an item failure, the item is immediately sent to the depot for repair and at the same time a replenishment order is issued according to the \((s-1,s)\) policy, where \(s\) denotes the order-up-to level. The unsatisfied demand of parts is backordered. When the replenishment order arrives at the base it is used to fill backorders, if any. Otherwise, it is added to stock. The time needed to transfer a spare from the depot to the base is assumed to be exponentially distributed. This assumption was validated in (Alfredsson and Verrijdt 1999) who show that it has a limited impact on the steady state average performance, such as the fill rate. In Section 5, using simulation we show that the survival function of the interval availability is not very sensitive to the order-and-ship time distribution at the points of survival function that are below the expected availability. We say that the system is operational if all the items are operational. Obviously, if an item fails and no spare is available at the base, the system will be malfunctioning and unavailable for use.

We consider a scenario inspired by a situation that we encountered at Thales Netherlands. There is one naval radar system at each of the \(N\) frigates (bases in our model). A system consists of \(M\) items. We assume that the \(j\)-th item fails according to a Poisson process with rate \(\lambda_j, j=1,\ldots,M\). Moreover, the failure of item \(j\) is independent of the other items. We assume that the replenishment lead time of the \(i\)-th item at the depot is exponentially distributed with rate \(\mu_j\). The replenishment lead time includes the time to transport the failed item from the base to the depot and the time to repair the item at the depot. We model the
depot repair shop as an ample server, i.e., it has infinite repair capacity. We also assume that the transshipment time of a spare part from the depot to base \( i \) is exponentially distributed with rate \( \mu_0i \). This means that all items at base \( i \) have the same transshipment time, however, the transshipment time may depend on the base where items are located. For sake of simplicity, we shall consider in the following the case where \( \mu_0i = \mu_0 \) for all \( i \).

Let \( s_{ij}, i=0,...,N, j=1,...,M \), denote the stock level of item \( j \) at base \( i \), where \( i=0 \) represents the depot and \( i=1,...,M \) represents the \( i \)-th base. Under the above assumption it is easily seen that the behavior of the system over time can be modeled as a continuous-time Markov chain. More precisely, since there is a finite number of spare parts in the network the continuous-time Markov chain is of finite size. Comparing the assumptions of our model and (VARI-)METRIC the difference is the exponentially distributed replenishment time and order-and-ship time, whereas order-and-ship times are deterministic and replenishment times have a general distribution in (VARI-)METRIC. In addition, (VARI-)METRIC considers an infinite population model, e.g., the number of jobs in a repair shop or the number of backorders can grow infinitely large. This of course occurs with a very small probability for scenarios of high expected availability. In the contrary with (VARI-)METRIC, we explicitly model the size of the installed base and the stock in the supply network, so that the demand for a spare part stops if the number of items in repair exceeds the total number of that spare parts in the network. This is more realistic and also facilitates the model numerical analysis for the interval availability distribution, since we limit the size of our continuous-time Markov chain.

Let \( A_i(T), i=1,...,N \), denote the interval availability of system \( i \) during \([0,T]\). Our objective is to find the survival function of \( A_i(T) \), i.e., the complementary cumulative distribution function of \( A_i(T) \). For this reason, we first compute the mean and the second moment of the interval availability as well as the probability that the interval availability equals 1, i.e., \( P(A_i(T)=1) \). Although we may also compute the probability mass in the point zero, \( P(A_i(T)=0) \), this is not really useful since for practical relevant problem instances it will be very close to zero. Next, using the three performance metrics as mentioned above we approximate the survival function of \( A_i(T) \) by a mixture of a
probability mass at one and a Beta distribution (so assuming zero probability mass in the point 0). Throughout this paper, we shall only focus on the interval availability of a tagged system, since we can analyze each system separately using the same method. For this reason, we shall drop the index $i$ in $A_i(T)$ and refer to it as $A(T)$: the interval availability of a tagged system at one of the bases. In addition, we shall refer to the stock level of item $j$ in the tagged system as $s_j$.

Since the failure processes of the different items can be considered to be independent of each other and the repair capacity is infinite, the different items on the tagged system behave mutually independent over time. Let $X_j(t)$ denote the state of item $j$ in the tagged system at time $t$, i.e., $X_j(t)=1$ if the item is operational at time $t$ and zero otherwise. Note that $X_j(t)=0$ if item $j$ fails and there is no spare part available at the base to replace the malfunctioning item. Let $BO_j(t)$ denote the number of item $j$ backorders of the tagged system at the depot. Let $TR_j(t)$ denote the number of items of type $j$ in transport from the depot to the tagged system. Therefore, the pipeline of item $j$ in the tagged system denoted by $PL_j(t)$ is equal to $BO_j(t) + TR_j(t)$. Note that $PL_j(t)$ depends on the stock on-hand at the depot. Furthermore, the depot stock depends on the failure processes of item $j$ in all the systems in the installed base including the tagged system. Let us denote $R_j(t)$ the total number of failed items of type $j$ in the depot repair shop. Note that backorders at the depot are served according to a FIFO discipline. Therefore, if $R_j(t) \geq s_{0j}$, i.e., on-hand stock in the depot is equal to zero, it is also necessary to keep track of the position of the tagged system backorders in the depot backorders list. Moreover, it is also necessary to know how many items of type $j$ are in transport from the depot to the tagged system. This is a complication that arises when computing the interval availability distribution which is not encountered in (VARI-)METRIC model for the steady state average availability. The previous complication makes a detailed Markov analysis difficult. For this reason, we shall propose an approximate three-dimensional finite-size Markov chain to represent the state evolution of item $j$ over time in the next section.
The tagged system is operational at time $t$ if $X_j(t) = 1$, for all $j=1,\ldots,M$. Let $O(T)$ denote the total sojourn time of the joint process $(X_1(t), X_2(t), \ldots, X_M(t))$ in state $(1,\ldots,1)$ during $[0,T]$. The interval availability of the tagged system can be seen as the fraction of time that the tagged system is operational, i.e., $A(T) = O(T)/T$. Note that the processes $X_j(t)$, for $j=1,\ldots,M$, are mutually independent and can be modeled as a Markov chain. Therefore, the joint process $(X_1(t), X_2(t), \ldots, X_M(t))$ is also a Markov chain.

A word on notation: Given that $A$ is a matrix, $A(i,j)$ denotes the $(i,j)$-entry of $A$. We use $I$ to denote the identity matrix of an appropriate size and use $\otimes$ as the Kronecker product operator defined as follows. Let $A$ and $B$ be two matrices then $A \otimes B$ is a block matrix where the $(i,j)$-block is equal to $A(i,j)B$. If $A$ is a square matrix, we denote its number of rows by $||A||$. We use $e$ to denote a column vector with an appropriate size and with all entries equal to one.

4 APPROXIMATION

In this section, we first approximate $X_j(t)$ with a three-dimensional continuous-time finite-state Markov chain. The main advantages of this approximation are that it gives accurate results and that it can be solved efficiently, see Section 5. Second, we represent the transition generator of the joint process $(X_1(t), X_2(t), \ldots, X_M(t))$ as function of the generators of $X_j(t)$, $j=1,\ldots,M$. The main approximations are as follows:

a. All the systems in the installed base, excluding the tagged system, have a constant annual demand for spare parts. This means, regardless of the state of these systems an item failure rate is constant over time. We note that the latter failure rate can be adjusted by the availability of item $j$, but numerical experiments show that this yields to a minor improvement of the results.

b. A depot repair completion at time $t$ of an item of type $j$ that is used to replenish a backorder of the tagged system occurs with a rate equal to $R_j(t)\mu_j * BO_j(t)/\left(R_j(t) - s_{0j}\right)^{+}$, where $(.)^{+} = \max(.,0)$. Note that $R_j(t)\mu_j$ is the depot repair
completion rate at \( t \) and \( (R_j(t) - s_{0j})^+ \) is the total number of backorders of item \( j \) at the depot at \( t \).

Let us consider the finite-state three-dimensional Markov chain \( \{(BO_j(t), TR_j(t), R_j(t)) : t \geq 0 \} \), referred to as \( AMC_j \). We note that the chain has a finite state space because of the finite number of stocks in the network. Recall that the pipeline of item \( j \) in the tagged system \( PL_j(t) = BO_j(t) + TR_j(t) \) and \( R_j(t) \) is the total number of type \( j \) items in the depot repair shop. Note that \( PL_j(t) \in \{0, \cdots, s_j + 1\} \), \( R_j(t) \in \{0, \cdots, s_{0j} + s_j + \cdots + s_{Mj} + M\} \), and \( BO_j(t) \leq (R_j(t) - s_{0j})^+ \), the total number of depot backorders of item \( j \). The process \( AMC_j \) has the following transitions:

1. A failure of item \( j \) in the tagged system if on-hand stock at the depot is positive, i.e., \( R_j(t) < s_{0j} \). It represents the transition from \( (0, TR_j(t), R_j(t)) \) to \( (0, TR_j(t) + 1, R_j(t) + 1) \) with rate \( \lambda_j \).

2. A failure of item \( j \) in the tagged system if no on-hand stock is available at the depot, i.e., \( R_j(t) \geq s_{0j} \). It represents the transition from \( (BO_j(t), TR_j(t), R_j(t)) \) to \( (BO_j(t) + 1, TR_j(t), R_j(t) + 1) \) with rate \( \lambda_j \).

3. A failure of item \( j \) in one of the systems in the installed based excluding the tagged system. It represents the transition from \( (BO_j(t), TR_j(t), R_j(t)) \) to \( (BO_j(t), TR_j(t), R_j(t) + 1) \), which occurs by approximation \( a \) with rate \( (N-1)\lambda_j \).

4. A depot repair completion of item \( j \) if on-hand stock at the depot is non-negative, i.e., \( R_j(t) \leq s_{0j} \). It represents the transition from \( (0, TR_j(t), R_j(t)) \) to \( (0, TR_j(t), R_j(t) - 1) \) with rate \( R_j(t) \mu_j \).

5. A depot repair completion of item \( j \) that is used to replenish a backorder of the tagged system, i.e., \( R_j(t) > s_{0j} \). It represents the transition from \( (BO_j(t), TR_j(t), R_j(t)) \) to \( (BO_j(t) - 1, TR_j(t) + 1, R_j(t) - 1) \), which occurs by approximation \( b \) with rate \( R_j(t) \mu_j \ast BO_j(t)/(R_j(t) - s_{0j})^+ \).
6. A depot repair completion of item $j$ that is used to fill a backorder of the systems in the installed based excluding the tagged system. It represents the transition from $(BO_j(t), TR_j(t), R_j(t))$ to $(BO_j(t), TR_j(t), R_j(t) - 1)$, which due to approximation $b$ occurs with rate $R_j(t) \mu_j \ast \left(1 - \frac{BO_j(t)}{(R_j(t) - s_{0j})^3}\right)$.

7. An arrival of an item $j$ from the depot to the base of the tagged system. It represents the transition from $(BO_j(t), TR_j(t), R_j(t))$ to $(BO_j(t), TR_j(t) - 1, R_j(t))$ with rate $TR_j(t) \mu_0$.

We emphasize that some transition rates are approximations. We evaluate the accuracy of these approximations numerically in Section 5 using simulation.

Let $G_j$ denote the transition generator of $AMC_j$. Since $AMC_j$ is a finite state Markov that is aperiodic and irreducible, we deduce that $AMC_j$ has a steady state probability distribution. Let $\pi_{m,n,l}(j)$ denote the steady state probability that $AMC_j$, which represents the evolution over time of the item $j$ that is used in the tagged system, is in state $(m,n,l)$. Let $\pi(j)$ denote the steady state probability distribution vector of $AMC_j$. The tagged system is operational if $m + n \leq s_j$ for all items $j = 1..M$, since there is no backorder of any item at the base then. On the other hand, when $m + n = s_j + 1$ there is one item $j$ backorder at the base, and so item $j$ is not available in the tagged system. Let $\Omega_j$ denote the state space of $AMC_j$. We split $\Omega_j$ into two disjoint subsets: $\Omega_{j}^o$ is the subset of operational states with $(m+n \leq s_j)$, and $\Omega_{j}^m$ is the subset of malfunctioning states $(m+n=s_j +1)$. Note that $\Omega_j = \Omega_{j}^o \cup \Omega_{j}^m$.

The steady state probability that item $j$ is operational in the tagged system equals

$$P(X_j = 1) = \sum_{n=0}^{s_j} \sum_{l=0}^{s_{0j} + \sum_{i=1}^{M} s_{ij}} \min_{(s_j-n(1-s_{0j}))^+(s_j-n(i-s_{0j}))^+} \sum_{m=0}^{\pi_{m,n,l}(i),}$$

where $X_j$ is the steady state of the process $X_j(t)$, i.e., $X_j = \lim_{t \to \infty} X_j(t)$. Note that the upper bound of $m$ in the previous equation is due to the fact that $m + n$ should be smaller than $s_j$ and the number of item $j$ backorders at the depot destined for the tagged system cannot
exceed the total number of backorders at the depot \((l - s_{0j})^+\). Throughout this paper, we shall assume that the \(AMC_J\) starts in steady state at time 0. Therefore, for all \(t \in [0, T]\) the chain \(AMC_J, j = 1, ..., M\), will remain in steady state, i.e., \(P(X_j = x) = P(X_j(t) = x), \forall t \in [0, T]\).

In the following, we shall use the uniformization method, which is extremely useful for computational purposes. The uniformization method transforms a continuous-time Markov chain with non-identical state leaving rates to an equivalent process in which the transition epochs are generated by a Poisson process at a uniform rate over all states. This is done by introducing additional virtual transitions from a certain state to the same state with the required rate. For more details see (Tijms 2003) and the references therein. Let \(P_j\) denote the transition probability matrix of the uniformized process of \(X_j(t), t \geq 0\). The matrix \(P_j\) reads

\[
P_j = I + \frac{1}{\nu} G_j,
\]

where \(I\) is the identity matrix of size equal to the size of \(G_j\), and \(\nu\) is given by:

\[
\nu > \max\left( |G_j(I, l)|, l = 1, ..., ||G_j|| \right),
\]

where \(||G_j||\) is the number of rows in square matrix \(j\).

Finally, let \(P_S\) denote the transition probability matrix of the joint uniformized process \((BO_1(t), TR_1(t), R_1(t)), ..., (BO_M(t), TR_M(t), R_M(t))\). Then, \(P_S\) is equal \(P_1 \otimes ... \otimes P_M\), see, e.g., (Rausand and Høyland 2004).

4.1 Performance Metric

In this section, we first derive in closed form expressions for \(E[A(T)], Var[A(T)],\) and \(P(A(T)=1)\). Next, we fit a probability distribution to these three performance metrics.

**Theorem 1**: The expected interval availability in \([0,T]\) is equal to the steady state availability of the system and is given by:
where $s_j$ is the stock level of item $j$ in the tagged system.

**Proof:** The system is operational at time $t$ if $X_j(t)=1$, $j=1,...,M$. Let $O(T)$ denote the total sojourn time of the joint process $(X_1(t),...,X_M(t))$ in the state $(1,...,1)$ during $[0,T]$. The expectation of $O(T)$ then reads

\[
E[O(T)] = \int_0^T E\left[1_{(X_1(u),...,X_M(u))=(1,...,1)}\right]du = \int_0^T P((X_1(u),...,X_M(u))=(1,...,1))du
\]

\[
= \int_0^T \prod_{j=1}^M P(X_j(u) = 1)du = \int_0^T \prod_{j=1}^M P(X_j = 1)du = T \prod_{j=1}^M P(X_j = 1),
\]

where the second equality in the first line is due to the independence of $X_1(t),...,X_M(t)$, and the second equality in the second line follows from the fact the system starts in steady state at time zero. Therefore, the system will remain in steady state for all $t > 0$.  

Note that the result in Theorem 1 seems to be straightforward. However, this is not the case since for the fill rate we know from the literature that its expected value over a finite period is larger than the steady state fill rate, see Section 2.

Before reporting our result on the variance of $A(T)$, let us introduce some notation. Let $\gamma_j$ denote a row vector of size equal to the cardinality of the state space $\Omega_j$. The vector $\gamma_j$ is obtained from the steady state probability vector $\pi(j)$ of $AMC_j$ by replacing the equilibrium probability of the malfunctioning states with zero. Let $f_j$ denote a column vector of size equal to the cardinality of the state space $\Omega_j$. The non-zero entries of $f_j$ are equal to one and they represent the operational states.

**Theorem 2:** The variance of the system interval availability in $[0,T]$ is given by:
\[\text{Var}[A(T)] = 2 \sum_{n=1}^{\infty} \frac{e^{-vt}}{(n+2)!} \sum_{i=1}^{n} (n-i+1) \prod_{j=1}^{M} \gamma_j(p_j)^i f_j + 2E[A(T)] \frac{e^{-vt} + vt - 1}{(vt)^2} - E[A(T)]^2.\]

**Proof:** Recall that \(O(T)\) denotes the total sojourn time of the joint process \((X_1(t), \ldots, X_M(t))\) in the state \((1, \ldots, 1)\) during \([0,T]\). Recall that \(P_s\), the transition probability matrix of the joint uniformized process \(((BO_1(t), TR_1(t), R_1(t)), \ldots, (BO_M(t), TR_M(t), R_M(t)))\), is equal to \(P_s = P_1 \otimes P_2 \otimes \cdots \otimes P_M\). Similarly, the probability vector that the joint process starts in an operational state at time zero reads
\[\gamma_s = \gamma_1 \otimes \gamma_2 \otimes \cdots \otimes \gamma_M.\]

Finally, let \(f_s\) denote the column vector defined as follows:
\[f_s = f_1 \otimes f_2 \otimes \cdots \otimes f_M.\]

It is well known that, see, e.g., (Horn and Johnson 1985)
\[(A_1 \otimes A_2 \otimes \cdots \otimes A_k, B_1 \otimes B_2 \otimes \cdots \otimes B_k) = A_1 B_1 \otimes A_2 B_2 \otimes \cdots \otimes A_k B_k\]

Therefore, it is readily seen that
\[\gamma_s(p_s)^i f_s = \gamma_1(p_1)^i f_1 \otimes \cdots \otimes \gamma_M(p_M)^i f_M = \prod_{l=1}^{M} \gamma_l(p_l)^i f_l,\]
where the last equality follows from the fact that \(\gamma_l(p_l)^i f_l\), for all \(l\), are positive real numbers.

Let \(\Omega_{so}\) denote the set of system operational states. According to Proposition 2 in Appendix I, we have that the variance of the cumulative sojourn time of the joint process in \(\Omega_{so}\) during \([0,T]\) is given by:
\[\text{Var}[A(T)] = 2 \sum_{n=1}^{\infty} \frac{e^{-vt}}{(n+2)!} \sum_{i=1}^{n} (n-i+1) \gamma_s(p_s)^i f_s + 2E[A(T)] \frac{e^{-vt} + vt - 1}{(vt)^2} - E[A(T)]^2.\]

Inserting \(\gamma_s(p_s)^i f_s\) by its value in the previous equation yields the desired result. \(\blacksquare\)
Similarly we can derive the third moment of $A(T)$, see Proposition 3 in Appendix I. However, we do not include the third moment in our approximation for the purpose of keeping the analysis simple and, moreover, we have a satisfying result with the consideration of the first two moments only, see Section 5.

The interval availability is equal to one if for all items $j$ the time until absorption of $ACM_j$ into the subset $\Omega_j^m$ (malfunctioning states set) is larger than $T$, given that $ACM_j$ starts at time 0 in $\Omega_j^o$ (operational states set). Let $\theta_j$ denote the row vector that only consists of the steady state probabilities of the operational states of $ACM_j$. We rearrange the generator $G_j$ of $ACM_j$ such that the operational states of $\Omega_j^o$ come first and then the malfunctioning states $\Omega_j^m$. We assume that the states of $\Omega_j^m$ are absorbing. Let $O_i$ denote the transient generator of rearranged $G_j$. Let $T_j^a$ denote the time until absorption into a state of $\Omega_j^m$. It is then well known that, see, e.g., (Neuts 1981)

$$P(T_j^a \geq T) = \theta_j \exp(TO_j)e.$$

**Theorem 3:** The probability that $A(T)=1$ is given by:

$$P(A(T) = 1) = e^{-T\sum_{i=1}^M v_i} \prod_{j=1}^M \theta_j \sum_{n=0}^{\infty} \frac{(v_j T)^n}{n!} (P_j^a)^n e,$$

where $P_j^a = I + O_j/v_j$, $e$ is a column vector of appropriate size with all elements equal to one, and $v_j > \max(\{|O_j(l,l)|, l = 1, ..., |O_j|\})$.

**Proof:** The proof follows right away by noting that:

$$P(A(T) = 1) = \prod_{j=1}^M P(T_j^a \geq T) = \prod_{j=1}^M \theta_j \exp(TO_j)e,$$

and, $\exp(TO_j) = e^{-v_j T} \sum_{n=0}^{\infty} \frac{(v_j T)^n}{n!} (P_j^a)^n$.

Note that the infinite sum in Theorem 2 and 3 can be truncated with a predetermined truncation error bounds, see (De Souza e Silva and Gail 1986; Tijms 2003).
Remark 1: In the special case where there is no any stock on-hand of items at the bases, the event $A(T)=1$ is only possible when there is no any items failure during $[0,T]$. Therefore, $P(A(T)=1)$ can be easily found as follows:

$$P(A(T) = 1) = E[A(T)] \prod_{j=1}^{M} e^{-\lambda j T}. $$

Remark 2: Note that it is hard to compute $P(A(T)=0)$. This is because a system is on failure if at least one item is on failure for every $t \in [0,T]$. Moreover, $P(A(T)=0)$ is negligible in practical problem instances of high expected availability. Therefore, we shall neglect this probability in the remainder of this paper. For that reason, we shall neglect it in the following.

4.2 Approximation of the survival probability function of $A(T)$

Until now we have computed the expectation and the variance of the interval availability $A(T)$ as well as the probability that the interval availability equals 1. We shall report now how to fit these metrics in a probability distribution that is a mixture of a probability mass at one and a Beta distribution. The choice for Beta distribution is made for the main reason that the interval availability and a Beta distributed random variable both have finite support.

The interval availability has probability mass at zero and one. According to Remark 2 the probability mass at zero shall be neglected. Therefore, we approximate the interval availability as follows:

$$A(T) = (1 - P(A(T) = 1)) * B + P(A(T) = 1),$$

where $B$ is a Beta distributed random variable bounded between zero and one. From the latter equation it readily seen that

$$E[B] = \frac{E[A(T)] - P(A(T) = 1)}{1 - P(A(T) = 1)},$$

$$E[B^2] = \frac{E[A(T)^2] - P(A(T) = 1)}{1 - P(A(T) = 1)}.$$

The probability density function of a Beta random variable reads
where $B(\alpha, \beta)$ is the beta function. Given that expectation and the variance of $B$ are known, simple calculus gives that

$$\alpha = \frac{(1 - E[B]) \cdot E[B]^2}{Var[B]} - E[B],$$

$$\beta = \alpha \left( \frac{1}{E[B]} - 1 \right).$$

**Theorem 4:** The survival function of the interval availability is given by:

$$P(A(T) \geq y) = (1 - P(A(T) = 1)) \int_x^1 f(x; \alpha, \beta) \, dx + P(A(T) = 1),$$

where $P(A(T)=1)$ is given in Theorem 3 and $f(x; \alpha, \beta)$, $\alpha$, and $\beta$ are given in (1)-(3).

5 NUMERICAL VALIDATION

In this section, we compare the results of our model with the simulation as function of the average system availability. Moreover, we consider different cases with different number of items per system ($M$). In the main scenario, one depot serves six bases. This scenario and its input parameters value are inspired by a case study done at Thales Netherlands. At each base, a single system is installed that is composed of $M=10,30,50$ items. The repairs are done at the depot and there is no repair possible at the bases. The repair time of item $j$ is exponentially distributed with rate $\mu_j = 1/MTR_{ij}$, where $MTR_{ij}$ is the mean time to repair item $j$. The order of magnitude of the $MTR_{ij}$ is between a few months to more than one year. In our model the order-and-ship time is exponentially distributed with mean 120 hours. Item $j$ fails according to a Poisson process with mean time between failures ($MTBF_{ij}$) equal to $1/\lambda_j,j = 1,\ldots,M$. The order of magnitude of $\lambda_j$ is between few times per year to a few times per hundred years. Each system is needed 3000 hours per year for missions. We are interested in the interval availability of a system during one year, i.e., $T=8760$ hours. The
implementation of the simulation is done in Plant Simulation v8.2. We used Matlab v7.8 to implement our model. We run the simulation and our model on a machine with dual core processor of 2.80GHz with 4GB RAM. For details on the different stock allocation, $MTBF_j$, and $MTTR_j$ in the nine cases considered see Appendix II.

In the following, we shall first validate our model and then analyze in Section 5.2 the impact of non-exponential order-and-ship on the interval availability distribution. Finally, in Section 5.3 we shall analyze the impact of the interval availability distribution on the stock allocation.

5.1 Model validation

In Figure 3, 4 and 5, we show the survival function of the interval availability using our model and the simulation with $M=10$, 30, 50, respectively. Note that in both the simulation and the model the order-and-ship times are exponentially distributed. Observe that our model has the highest accuracy for the cases where $M=10$ and 30 and where $E[A(T)]$ is larger than 80%. Our model predicts very well $E[A(T)]$ and $Var[A(T)]$ for all the cases, see the second and third row in Table 2, 3 and 4 for details. Note that for all the different cases considered the difference of $P(A(T) \geq x)$, with $x \geq E[A(T)]$, obtained using the simulation and our model is larger than -0.05 and smaller than 0.04, as indicated in Table 2, 3 and 4. Finally, we should mention that the computation time of our model is less 500ms for all the considered cases.

Figure 1: Interval availability survival function with $M=10$ in case: 1. $E[A(T)] = 70\%$, 2. $E[A(T)] = 83\%$, and 3. $E[A(T)] = 92\%$. 
Figure 2: Interval availability survival function with $M=30$ in case: 4. $E[A(T)]=72\%$, 5. $E[A(T)]=83\%$, and 6. $E[A(T)]=90\%$.

Figure 3: Interval availability survival function with $M=50$ in case: 4. $E[A(T)]=72\%$, 5. $E[A(T)]=81\%$, and 6. $E[A(T)]=91\%$.

5.2 Exponential vs. deterministic and uniform order-and-ship time

In this section we shall show that the exponential assumption of the order-and-ship time considered in our model has almost no impact on the survival function of the interval availability, especially, on $P(A(T)\geq x)$ with $x \leq E[A(T)]$. Using the simulation we shall compare the case with exponentially distributed order-and-ship time with the deterministic and uniformly distributed order-and-ship time. All the three distributions have the same expectation equal to 120 hours. The uniform distribution has a finite support in the interval [108,132]. Figure 4 displays the survival function of the interval availability with the three distributions. Observe that the order-and-ship time distribution has only an impact on the tail of the survival function, i.e., on $P(A(T)\geq x)$ with $x \geq E[A(T)]$. In addition, the survival function in the deterministic and uniform case are almost the same and both have some discontinuity points in the tail. Furthermore, using simulation we also find that the repair time distribution has a minor impact on the survival function of the interval availability.

![Figure 4](image_url)

Figure 4: Interval availability survival function for deterministic, exponential, and uniform order-and-ship time with $M=50$ in case: 8. $E[A(T)] = 80\%$, 9. $E[A(T)] = 92\%$.

5.3 Impact on stock allocation

In this section, we show that the use of the interval availability probabilities as goal instead of the expected availability may influence the stock allocation in the network. We shall
consider two different stock allocations with the same expected availability and total number of items, however, with a different survival probability of the interval availability. We consider the following simple scenario: we have six systems each of them consists of two items with a mean time between failures equal to 3640 and 1905 hours and both have a mean time to repair that is equal to 2160. The order-and-ship time is equal to 120 hours. The price of the items are equal to one unit. For a given stock investment of 11 units, METRIC gives that the optimal stock allocation at depot is (4, 6), at base one (1, 0), and at the other bases (0, 0). Using our model we find that for the previous stock allocation the expected system availability at base one is 97.7% and at the rest of bases is equal to 96.5%. Therefore, the expected system availability is equal to 96.7%. The survival probability that $A_i(T) \geq 90\%$, the interval availability of base one larger than 0.9, is equal to 97.5% and for the rest of systems it is equal to 93.9%. Therefore, on average the survival probability at percentile 0.9 is equal to 94.5%. For the stock allocation at depot (5, 6) and at bases (0, 0), the expected system availability is equal to 96.6% and the survival availability of the systems at point 90% is equal to 95.0%. Observe that the two different stock allocations have almost the same expected availability and total number of items, however, the second allocation has a higher survival probability. Therefore, we conclude that the inclusion of the survival probability of the interval availability in the stock allocation optimization may lead to a different stock allocation compared to the METRIC approach.

6 CONCLUSION AND DIRECTIONS FOR FURTHER RESEARCH

In this paper we analyzed the interval availability of a two-echelon network that supports multi-item systems. We proposed an efficient analytical approximation that is based on a Markov chain analysis. From Markov chain analysis we computed in closed and exact form the expected, the variance, and the probability of hundred percent interval availability of the system. Using the previous three performance metrics we approximate the survival function of the interval availability with a mixture of a probability mass at one and a Beta distribution. The simulation result shows that our model has accurate results especially for high expected interval availability.
As a future research we plan to include our model in a optimization procedure of interval availability probability subject to a constraint on the total investment in the spare parts. Other constraints could also be added like the penalty costs of not meeting the SLA on interval availability. Besides, the extension of the model for multi-echelon supply network with more than two levels and possibly the multi-indenture case are also important. Since in some practical cases we encountered a case with multi-indenture, three-echelon network. Moreover, the restriction in our model for only repairing the failed items at the depot should be relaxed.

Appendix I: TECHNICAL PROOF

In this Appendix we derive the first three moment of the cumulative sojourn time in a subset of the states of a continuous time Markov chain during an interval \([0,T]\). Let \(G\) denote the transition rate generator of a continuous-time Markov chain \(X(t)\) with finite state space \(\Omega\) of size \(|\Omega|\). We assume \(X(t)\) has a steady state distribution and that \(X(0)\) is distributed according to the steady state distribution. Let \(x_i\) denote the steady state probability \(X(\infty)=i\). We denote by \(G(l,m)\) the \((l,m)\)-entry of \(G\). Let us define the matrix \(P\) as follows:

\[
P = I + \frac{1}{\nu} \hat{G},
\]

where \(I\) is the identity matrix of size \(|\Omega|^2\), and \(\nu\) is given by:

\[
\nu > \max\left(|G(l,l)|, l = 1, ..., |\Omega|\right).
\]

\(P\) can be interpreted as the transition probability matrix of the uniformized process of \(X(t), t \geq 0\), see, e.g., (Tijms 2003).

Let \(O(T)\) denote the total sojourn time during \([0,T]\) in a subset \(\Omega_o \subset \Omega\). It is then well known that the cumulative distribution of the sojourn time in \(\Omega_o\) reads, see, e.g., (De Souza e Silva and Gail 1986; Tijms 2003),

\[
P(O(T) \leq x) = \sum_{n=0}^{\infty} e^{-\nu T} \frac{(\nu T)^n}{n!} \sum_{k=0}^{n} \alpha(n,k) \sum_{j=k}^{n} \binom{n}{j} \left(\frac{x}{T}\right)^j \left(1 - \frac{x}{T}\right)^{n-j}, \quad 0 \leq x < T,
\]

\[
P(O(T) = T) = \sum_{n=0}^{\infty} e^{-\nu T} \frac{(\nu T)^n}{n!} \alpha(n, n + 1),
\]

where \(\alpha(n,k)\) is the probability that the uniformized process visits \(k\) times the subset \(\Omega_o\) during \([0,T]\) given that it makes \(n\) states transitions in \([0,T]\). Note that the interval availability \(A(T):=O(T)/T\).
Let us denote $P_o$ the probability matrix with $j$-th column equal to the $j$-th column of $P$ if $j \in \Omega_o$ otherwise the $j$-th column is equal to a vector of zeros. Let $P_f = P - P_o$. Conditioning on $j$ the state of the Markov chain at time $T$ the probabilities $a(n,k,j)$ can be computed recursively. Let $\Gamma(n,k)$ denote a row vector with $j$-th entry equal to $a(n,k,j)$. It is easy to see that $\Gamma(n,k)e = a(n,k)$. The vector $\Gamma(n,k)$ then satisfies the following recursion, see (De Souza e Silva and Gail 1986),

$$\Gamma(n,k) = \Gamma(n-1,k-1)P_o + \Gamma(n-1,k)P_f, n \geq 1, k \geq 1.$$  

$$\Gamma(n,0) = \Gamma(n-1,0)P_f, n \geq 1, k = 0,$$

with the initial conditions:

$$\Gamma(0,0) = (x_1, ..., x_\Omega)P_f,$$

$$\Gamma(0,1) = (x_1, ..., x_\Omega)P_o.$$

**Proposition 1:** The $m$-th moment $O(T)$ is given by:

$$E[A(T)^m] = \sum_{n=0}^{\infty} e^{-\nu T} \frac{(\nu T)^m}{(n + m)!} \sum_{k=1}^{n+1} \alpha(n,k) \prod_{l=k}^{k+m-1} l$$

**Proof:** The $m$-th moment follows immediately by noting that

$$E[O(T)^m] = m \int_0^T x^{m-1} P(O(T) \geq x) dx,$$

$$\int_0^T x^m \left( \frac{x}{T} \right)^j \left( 1 - \frac{x}{T} \right)^{n-j} dx = T^m \frac{(n-j)!(j+m-1)!}{(n+m)!},$$

and

$$\sum_{j=k}^{n} \frac{(j + m - 1)!}{j!} = \frac{1}{m} \left[ \frac{(n+m)!}{n!} - \frac{k(m+k-1)!}{k!} \right].$$

We deduce from Proposition 1 that it remains to compute $\sum_{k=0}^{n+1} \alpha(n,k) \prod_{l=k}^{k+m-1} l$ in order to find $E[A(T)^m]$. In order to do so we shall follow an approach based on generating function. Let us multiply (4) by $x^k$ and summing the result over all $k=0,\ldots,n+1$ we find that
\[ \sum_{k=0}^{n+1} \Gamma(n, k)z^k = \Delta_0(z)(zP_o + P_f)^n = (x_1, ..., x_{|\Omega|})(zP_o + P_f)^{n+1}, n \geq 0. \] (5)

In the following we restrict the derivation to the second and third moment of \( A(T) \). Taking the first derivative of (5) according to \( z \) at point one and multiplying the result with the column vector \( e \) we find that
\[ \sum_{k=1}^{n+1} k\alpha(n, k) = (n + 1) (x_1, ..., x_{|\Omega|}) \sum_{i \in \Omega_o} x_i, \] (6)
where we used that \( P, e = e \) and \( (x_1, ..., x_{|\Omega|})P = (x_1, ..., x_{|\Omega|}) \). Taking the second order derivative of (5) according to \( z \) at point one and multiplying the result with \( e \) we find that
\[ \sum_{k=1}^{n+1} k(k - 1)\alpha(n, k) = 2p_0 \sum_{i=1}^{n} (n - i + 1) p^i e_0, \] (7)
where \( p_0 = (x_1, ..., x_{|\Omega|})P_o \), i.e., \( p_0 \) is the column vector with \( i \)-th entry equal to \( x_i \) if \( i \in \Omega_o \) and zero otherwise, and \( e_0 \) is the column vector with \( i \)-th entry equal to 1 if \( i \in \Omega_o \) and zero otherwise. Finally, the third derivative of (5) at point one gives that
\[ \sum_{k=1}^{n+1} k(k - 1)(k - 2)\alpha(n, k) = 6p_0 \sum_{i=1}^{n-1} \sum_{j=1}^{n-i} (n + 1 - i - j) p^{i-1} p^j e_0. \] (8)

The sum of (7) with two times (6) gives \( \sum_{k=0}^{n+1} k(k + 1)\alpha(n, k) \) right away. Moreover, 
\[ \sum_{k=0}^{n+1} k(k + 1)(k + 2)\alpha(n, k) = (8) + 6 \cdot [(6) + (7)]. \] We are now ready to show our main results.

**Proposition 2:** The second moment of the fraction of time that the Markov chain \( X(t) \) sojourns in the subset \( \Omega_o \) during \([0, T]\) is given by:
\[ E[A(T)^2] = 2 \sum_{n=1}^{\infty} e^{-\nu T} \frac{(\nu T)^n}{(n + 2)!} p_0 \sum_{i=1}^{n} (n - i + 1) p^i e_0 + 2 \sum_{i \in \Omega_o} x_i \frac{e^{-\nu T} + \nu T - 1}{(\nu T)^2}, \]
where \( x_i \) is the steady state probability of the Markov chain in state \( i \), \( p_0 \) is the column vector with \( i \)-th entry equal to \( x_i \) if \( i \in \Omega_o \) and zero otherwise, and \( e_0 \) is the column vector with \( i \)-th entry equal to 1 if \( i \in \Omega_o \) and zero otherwise.
Proposition 3: The third moment of the fraction of time that the Markov chain $X(t)$ sojourns in the subset $\Omega_0$ during $[0,T]$ is given by:

$$
E[A(T)^3] = 6 \sum_{n=0}^{\infty} e^{-\nu T} \frac{(\nu T)^n}{(n+3)!} p_0 \sum_{i=1}^{n-1} \sum_{j=1}^{n-i} (n-i-j+1) p^{i-1} p_j e_0 + \\
12 \sum_{n=0}^{\infty} e^{-\nu T} \frac{(\nu T)^n}{(n+3)!} p_0 \sum_{i=1}^{n} (n-i+1) p^i e_0 + \\
12 \sum_{i \in \Omega_0} \frac{\nu T - 2 + (\nu T + 2) e^{-\nu T}}{(\nu T)^3}.
$$

Proof: The results follow right away by replacing $m$ by two and three in Proposition 1 and using equation (7) and (8).

APPENDIX II: SIMULATION DETAILS

The mean time between failures, $MTBF$, of the items in the cases with $M=50$ items are given as follows: $(MTBF_1 \cdots MTBF_{50}) = (5280 \ 3360000 \ 38100 \ 32400 \ 3180 \ 333000 \ 185100 \ 825000 \ 339000 \ 1095000 \ 280200 \ 726000 \ 41400 \ 223800 \ 288300 \ 195900 \ 348000 \ 564000 \ 27780 \ 265200 \ 26520000 \ 42900000 \ 26520000 \ 3330000 \ 133200000 \ 1332000000 \ 2652000000)$.

Note that in the cases with $M=10$ and 30 we respectively take the first 10 and 30 elements of the latter vector.

The mean time to repair, $MTTR$, of the items in the cases with $M=50$ items are given as follows: $(MTTR_1 \cdots MTTR_{50}) = (2160 \ 5760 \ 2160 \ 2160 \ 2160 \ 2160 \ 4320 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 2160 \ 4320 \ 2160 \ 2160 \ 2160 \ 2160 \ 4320 \ 2160 \ 3600 \ 3600 \ 3600 \ 5760 \ 5040 \ 4320 \ 5040 \ 5040 \ 5040 \ 5040 \ 5040 \ 6480 \ 6480 \ 6480 \ 6480 \ 6480 \ 5760 \ 2160)$. Note that in the cases with $M=10$ and 30 we respectively take the first 10 and 30 elements of the latter vector.
The stock at the depot is a vector represented as \( (s_{01}, \ldots, s_{0M}) \).

**Case 1**

\( M=10, \) depot stock = \( (1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 2**

\( M=10, \) depot stock = \( (1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 0 \ 0 \ 0 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 3**

\( M=10, \) depot stock = \( (2 \ 1 \ 1 \ 2 \ 0 \ 0 \ 0 \ 0 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 4**

\( M=30, \) depot stock = \( (1 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 5**

\( M=30, \) depot stock = \( (2 \ 2 \ 2 \ 1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 6**

\( M=30, \) depot stock = \( (7 \ 1 \ 2 \ 2 \ 1 \ 1 \ 1 \ 1 \ 0 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 1 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 7**

\( M=50, \) depot stock = \( (2 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 8**

\( M=50, \) depot stock = \( (3 \ 2 \ 2 \ 2 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).

**Case 9**

\( M=50, \) depot stock = \( (2 \ 1 \ 2 \ 3 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 1 \ 0 \ 1 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 0 \ 1 \ 1 \ 1 \ 1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 4 \ 4 \ 1 \ 1 \ 1 \ 1 \ 1 \ 2 \ 1 \ 1 \ 0 ) \), base stock = \( (0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \) ).
