while curvature sensing is generally conserved throughout the membrane binding region of α-Syn, curvature generation requires specific binding domains. These results will help to form a model for the interplay between α-Syn membrane binding activity and membrane remodeling and may have implications for understanding both α-Syn’s native role as well as its contribution to PD.

Determination of Primary Nucleation Mechanisms of α-Synuclein Amyloid Aggregation
Protein conformational diseases represent a class of pathologies in which specific peptides or proteins form aberrant self-assemblies that constitute the hallmark of several neurodegenerative diseases. Specifically, the formation of intra-neuronal inclusions of the protein α-synuclein (α-Syn) is associated with the pathogenesis of Parkinson’s disease (PD). A great interest is in the early stages of α-Syn aggregation, for which soluble monomeric proteins are converted into fibrillar nanostuctures. It has been shown that at these stages many parallel and competing pathways take contemporaneously place and it is currently very difficult to address on these mechanisms by using standard techniques of molecular investigations. In order to overcome the limitations of standard approaches, we employed ensemble-averaged kinetic studies coupled with microdroplet technology in order to characterize the primary nucleation early stages of α-Syn amyloid formation and therefore to elucidate the fundamental mechanisms underlying this phenomenon. Testing different aggregation conditions, we have been able to understand that the primary nucleation mechanism underlying α-Syn aggregation is not homogeneous, whereas it is catalysed by different factors, including air/water surface interactions. The full characterization of all the processes involved in the aggregation mechanism of α-Syn will be fundamental for devising new and innovative therapeutic strategies against PD. Indeed, based on our analysis, we expect that it will be possible to design and screen pharmacological compounds able to selectively inhibit the nucleation steps that trigger either the overall of the process or specifically the formation of the toxic aggregated species.

Oligomerisation of Alpha-Synuclein at Physiological Concentrations
Marija Ilijina. Cambridge University, Cambridge, United Kingdom.
Alpha-synuclein is a small intracellular protein naturally abundant in the brain at low-micromolar concentrations. Its fibrillar aggregates are the major constituents of intracellular inclusions, known as Lewy bodies, which are the pathological hallmarks of Parkinson disease and related neurodegenerative disorders. However, increasing evidence suggest that oligomers, rather than fibrils, are the most toxic and damaging to brain neurons. Single molecule FRET can be used to detect and characterise the low levels of heterogeneous oligomers formed during protein aggregation. In this presentation, I will discuss the recent results of in-vitro studies of alpha-synuclein oligomer formation at physiologically-relevant concentrations using single-molecule FRET spectroscopy and show how these experiments reveal the key microscopic reactions taking place during the aggregation of alpha-synuclein.

Single-Molecule Spectroscopy Reveals Polymer Effects of Disordered Proteins in Crowded Environments

It is currently unclear how the crowded cellular milieu affects the structural distributions of intrinsically disordered proteins (IDPs). Here we employ single-molecule Förster resonance energy transfer (FRET) to quantify the effect of molecular crowding on four disordered proteins with very different degrees of charge-induced expansion. For a variety of crowding agents (PEG, PVP, Dextran, PVA), an increasing collapse of the polypeptide chains is observed with increasing concentrations of crowder, as expected from simple considerations, such as scaled particle theory. However, we also observe an increasing collapse with increasing size of the crowder, the opposite of what scaled particle theory predicts. Interestingly, the observations can be rationalized quantitatively within the framework of Flory-Huggins theories that take into account the polymeric properties of both the disordered proteins and the crowder. The results provide a step towards understanding the behavior of IDPs and denatured proteins in the presence of polydisperse co-solutes as those characteristic of the cellular environment.

The pathological hallmark of Parkinson’s disease is the presence of insoluble protein deposits in the brain, which are formed when specific protein molecules misfold and aggregate into highly ordered fibrils. In Parkinson’s disease, the deposits are primarily made up of alpha-synuclein, a protein whose major function is not fully known. Rather than the fibrils themselves being toxic, evidence now points towards the smaller, soluble oligomers formed in the initial stages of the process as being the culprit. We have developed a novel single-molecule fluorescence technique to detect and characterise the oligomers of alpha-synuclein. Using this methodology, we are able to identify the cytotoxic species, and apply these species to primary neuronal cultures to investigate their damaging effects.

α-Synuclein (αS) is a 140 aa intrinsically disordered and amyloidogenic protein. Its physiological functions are unclear, but are believed to be connected to the interaction with synaptic vesicles or membranes of other organelles. The sequence of αS shows partial 11 amino acid periodicity that induces atypical 3/11 helix conformation on membranes. Fluorescence studies of tryptophan mutants of αS point to a flexible break at residues 52-54 between two helical domains. Deletion of this flexible 4 aa fragment between two groups of 11 aa repeats does not significantly affect αS membrane binding but strongly decreases the protein aggregation and fibril formation propensity. Moreover, the deletion mutant inhibits aggregation of wildtype αS, likely by hindering the fibril growth, since the mutant does not appear to co-aggregate into fibrils with wild-type αS.
Introducing additional 11 amino acid repeats into the αS sequence increases affinity of the modified protein to membranes and slows down the protein aggregation. We believe that the 11 amino acid repeats in the αS sequence play a key role in αS’s ability to switch between a helical conformation on membranes and β-sheets in fibrils.
